2.—Ohmann-Dumesnil reports a case of **arsenical poisoning** in a young woman of 26 years, who took a teaspoonful of "rough on rats" with suicidal intent. The case

is reported especially on account of the **arsenical dermatitis** which developed. The lips and nose were swollen and the eruption vesicular, while some pustules appeared on the face and buttocks. The vermilion of the lips presented no lesions, but were hot and dry. The **localization** of the eruption is of interest, together with the fact that the dermatitis followed a single large dose of the drug, while it usually appears in cases where small repeated doses of the drug are taken. The case terminated in recovery. [T.L.C.]

3.—A. D. Blackader discusses the now much mooted question of the advantages and disadvantages of **sterilization of milk**. He concludes that by sterilization the proteids are probably modified and rendered less digestive. There is also a probable combination of the saline ingredients with the proteids, and the salts assume a condition in which they are less readily absorbed. Natural ferments which assist in the gastric digestion are possibly destroyed. Again an alteration takes place in the emulsion, normal to milk, which may also have a distinct effect of lessening the digestibility of cow's milk by the infant. It is important to keep **sterilized milk** at a continuous low temperature and to use milk soon after sterilization. Blackader recommends using fresh milk carefully drawn and in which lactic-acid-producing bacteria in such small numbers as to induce no important alterations. This milk should not be sterilized, but when we are not sure of our supply it is advisable to sterilize at the lowest temperature, namely 60° C. maintained for 15 minutes. [T.L.C.]

5.—McRae first discusses the **comparative frequency of appendicitis in men and women**, and thinks that the disease is much more common in the latter sex than is generally supposed, because of the frequency with which this disease is mistaken for inflammation of the tube and ovary of the right side. Several of his patients had had treatment directed to the pelvic organs for a more or less prolonged period. In making a diagnosis between inflammation of the tube and ovary and of the appendix, it will be found that the pain of appendicitis is more sudden in its onset, and very much more acute than that of pelvic disease; it is frequently accompanied with nausea, and muscular spasm is usually marked; the general disturbance is greater, and the progress of the disease is more rapid. An intact hymen argues very strongly for appendicitis. When there is doubt, and the symptoms are aggressive, it is much safer to operate than to delay. In 2 of his cases, MacRae performed appendectomy and nephrorrhaphy through the same incision. He then reports in detail 8 operations done in the interval between attacks, and 7 operations done during acute attacks. All of these cases were successful. [J.H.G.]

6.—Kerrison discusses the frequency, symptoms, and diagnosis of **pharyngeal adenoids** in detail, and concludes his article as follows: 1. That pharyngeal adenoids in children are very much more common than they are generally supposed to be. 2. That cases of moderate development are often not recognized. 3. That adenoid growths of moderate size, though not necessarily accompanied by marked symptoms at the time of their development, are often responsible for grave conditions felt during adolescence and adult life. 4. That unless removed, pharyngeal adenoids are in nearly all cases accompanied by more or less impairment of hearing. 5. That the presence of adenoids adds greatly to the gravity of intercurrent diseases and increases the patient's susceptibility to the germs of tuberculosis and diphtheria. 6. That the periodical examination of children for the presence of adenoids should therefore become a routine measure of prophylaxis. 7. That cases of moderate development, no less than those in which the growths are of large size, demand prompt surgical treatment. 8. That the treatment should aim at complete ablation or removal of the growth, which in most cases is best accomplished with the patient under the influence of a general anesthetic. [J.H.G.]

Medical Record.

February 2, 1901. [Vol. 59, No. 5.]

1. Radical Cure of Inguinal Hernia. A. M. PHELPS.
2. The Treatment of Puerperal Fever. H. J. BOLDT.
3. An Operation for the Relief of Stoppage of the Tear Passage, Abscess of the Sac, etc. ERASMUS A. POND.

1.—Phelps gives a brief history of the operations for hernia and then thoroughly discusses the modern methods of **treatment of inguinal hernia**, giving especial attention to the operations of Bassini and Halsted. He claims that many relapses follow these operations because so much destruction of the normal muscular tissue has taken place from the long continuance of the condition that it is impossible, by these methods, to sustain the pressure from within. An additional reason why relapse takes place after these operations is that there is no effort made on the part of the surgeon to reproduce the tissue which has been destroyed by pressure, and to prevent the stretching of the connective tissue which always results from wound-healing. McBurney's operation has also been followed by the most lamentable relapses. Phelps proposes a new operation for which he claims the following points of originality: 1. The reproduction of large masses of inflammatory material to restore the abdominal parietes, and the introduction of a fine silver wire filigree throughout the entire inguinal canal, over the transversalis fascia, which adds to the strength of the weakened abdominal parietes and prevents the new material from stretching. 2. Cutting off the hernial sac, and retreating from the operation exactly as from any abdominal operation, stitching up the peritoneum and transversalis fascia with a continued suture of fine silver wire. 3. The use of fine silver wire with a continued suture. To sterilize the wire, after it has been thoroughly boiled or steamed, he throws it into pure carbolic acid a few minutes before the operation, after which he dips it into alcohol, holds it over an alcohol lamp, and burns the alcohol upon the wire. Drainage should be avoided if possible; but if necessary in thick, abdominal walls with much fat, a glass drain is the best. [W.A.N.D.]

2.—Boldt, in speaking of the **treatment of puerperal fever**, classes under this term only those fevers which are caused by the entrance into the system of the puerperal woman of pathogenic microorganisms, or toxins, from some part of the genital tract. In the treatment prophylaxis is the most important. It is, therefore, imperative to observe the rules of antiseptics in obstetrics. It is essential that the patients be kept at perfect rest, and attention must be directed to the seat of primary entrance of the fever-producing agents. When the seat of the infection is in the uterus, this organ is found enlarged and relaxed and the cervical canal generally admits of the introduction of the index finger. All retained products of conception must be removed under antiseptic precaution and an intrauterine douche is always advisable before and after manipulations within the uterus. Continuation of fever and purulent secretions from the uterus indicate repetition of the intrauterine irrigation. Vaporization is more effective on infection-elements in the deeper structures of the uterus. The antiseptic and hemostatic properties of steam are well known, but its dangers must not be lost sight of. When applied to the interior of the uterus it causes deep destruction of the uterine tissue when used sufficiently long to render pathogenic germs situated in the muscular structure of the organ inert. Boldt believes that acute bacteremia is always fatal. Chronic bacteremia must be treated according to the indications in the individual patient. [W.A.N.D.]

3.—Pond describes an operation for the relief of **lachrymal obstruction and suppurative conditions** of the lachrymonasal passages. He believes that it is superior to probing. A long silver probe with an eyelet is threaded with coarse silk and is passed into the canal until it emerges from the nose, whereupon the two ends of the thread are tied. He leaves the slitting of the canaliculus to the judgment of the operator. It is preferable to tie a large knot so that by pulling the string through the canal, which is done two or three times a day, a larger opening is produced. The string is removed in one week. The operation can generally be performed under cocaine anesthesia, although ether may have to be employed. Three cases showing good results are appended. [M.R.D.]

Medical News.

February 2, 1901. [Vol. lxxviii, No. 5.]

1. An Historical Sketch of the Jefferson Medical College of Philadelphia.

2. Fatty Degeneration of the Heart. THOMAS E. SATTERTHWAITE.
3. A Case of Puerperal Sepsis from Retained Lochia (Lochiometra), with Remarks. GEORGE P. SHEARS.
4. Medical and Sociological Aspects of the Galveston Storm. H. A. WEST.

2.—Thomas E. Satterthwaite takes up the subject of **fatty degeneration of the heart** and illustrates his division of the condition into three arbitrary stages by a number of cases. The first stage is that one in which the prognosis is most favorable; that is, if the patient does not yield to the primary disease he will probably recover with a sound heart if properly treated. In the second stage prognosis is not good for total arrest of the fatty process, but much improvement may be brought about. The third stage is marked by profound implication of the internal viscera, the prognosis is unfavorable and the end may be expected within a few months. Fatty degeneration of the heart is a common affection, but it is not to be classed as a disease sui generis but as a process attending nonvalvular as well as valvular affections. It is caused by fevers, toxemias, dyscrasias, disorders of nutrition and mechanical injuries, but it may be a physiologic process, as in senility or after parturition. [T.L.C.]

3.—Shears reports a case of **puerperal sepsis or true lochiometra**, not so much because of its rarity but because, he claims, that the English and American textbooks ignore the subject altogether. He states that the sensation communicated to the palpating finger in these cases is a peculiar one. The uterus has a boggy, semi-elastic feel, which has been compared to that of the pregnant uterus. He confirms the statement of Oulshausen and Veit that without bacteriological examination there is no positive diagnostic sign of this condition except in those cases in which a history of retained placenta establishes the diagnosis of purid (sapremic) endometritis. In most cases the diagnosis can be made with a reasonable degree of safety by a process of exclusion. In sepsis from retained lochia, the enlargement of the uterus disappears with the removal of the cause. The possible, though rare, occurrence of this form of sepsis from retroflexion of the puerperal uterus should not be forgotten. A bacteriologic examination should be restricted to those cases in which it is necessary, for purposes of treatment, that the diagnosis be made with absolute certainty. The streptococcus is present not only in severe cases but in all grades of mild cases, and to wait until the bacteria are found in the blood-current, as has actually been suggested, is to wait too long. [W.A.N.D.]

4.—West discusses the **Galveston storm** from its **medical and sociological aspects**. After the hurricane and due to the overcrowding and high temperature, as well as the lack of sanitary measures, insects, especially flies, became a pest. It was observed that despite the fact that mosquitoes had always been a pest in Galveston, malaria was very uncommon. After the storm, however, the disease became very prevalent. Most of the cases were of the tertian form. A small proportion were estivoautumnal and pernicious. Gastrointestinal catarrh and dysentery became epidemic. Typhoid fever was also very prevalent. Scarlet fever, diphtheria, influenza, and dengue appeared, but not in epidemic form. Many cases of mixed infections, as of malaria and dysentery coexisting in the same patient, are reported. West points out the need of proper sanitary measures, especially the disposal of the city sewage. [T.L.C.]

Boston Medical and Surgical Journal.

1. The Treatment of the Later Phases of Heart Diseases. JOHN L. HEFFRON.
2. Peritonsillar Abscess. F. C. COBB.
3. Retropharyngeal Abscess in the Adult. J. L. GOODALE.

1.—Heffron contributes a paper on the **treatment of the later phases of heart diseases**. When compensation has failed, the first indication is to relieve the heart of all extra work, which is best accomplished by rest in bed. In the second place, the volume of blood to be propelled by the heart should be diminished as much as possible. For this purpose the hydragogue cathartics are the best, and of

these the most preferable is elaterium, followed in order of preference by calomel and the salines. In the third place, the distressing nervousness of the patient, which increases the irritability of an already overburdened heart, must be controlled. For this purpose ice-bags locally, codein and morphin may be used. The author believes that heroin is a modern fraud. In cases in which the nervousness is not extreme he has had gratifying results from the use of the extract of cannabis indica. The diet must, of course, be controlled. When failure of compensation has resulted in dropsy, it is sometimes necessary to withdraw the fluid by mechanical means before drugs will exert their physiologic action. The author believes in the use of the hot-air cabinet in order to promote the excretion of sweat, and in digitalis, squill or potassium acetate to stimulate the secretion of urine. In order to aid in the complete retrograde metamorphosis of waste matter, the author has found the systematic administration of oxygen to be of very great value. While spartein, cactus, convallaria, strophanthus, and adonis vernalis are useful, digitalis is the drug that can be the most often depended upon. In cases of sudden failure of cardiac power, drugs that act quicker than digitalis, such as nitroglycerin, alcohol, ammonia, and strychnin are used. Oertel's method of hill-climbing, and the Schott method of treatment by carbonated baths are extolled. [J.M.S.]

2.—Cobb believes that **peritonsillar abscess** is the result of infection by the microorganisms of acute tonsillitis. The suppuration may occur in the tissue around the tonsil or in a space described by Chari as the pharyngomaxillary fossa. This space is bounded by the tonsil, the internal pterygoid muscle and the palatine arches. It contains the great vessels and is divided into an anterior and a posterior portion by the stylopharyngeus muscle and its fascia. The conditions that may be confused with peritonsillar abscess are sarcoma and syphilis. Cases that are untreated usually rupture spontaneously between the pillars of the fauces. Cases are on record in which the pus has made its way into the posterior portion of the pharyngomaxillary fossa, and thence into the mediastinum, with fatal results. Thrombosis of the large veins and pyemia have also resulted. The author believes that the knife only can give relief and that drugs, such as the salicylates and aconite, on account of their depressing influence, contribute to the exhaustion that follows the disease. In order to hasten the formation of pus he employs hot-water gargles. [J.M.S.]

3.—Goodale reports the case of a man, aged 18 years, who presented a swelling in the back of his throat which had gradually increased in size for 4 weeks. The growth was not accompanied by fever nor by other disturbance than dysphagia. Examination of the throat showed a fluctuating swelling on the posterior wall of the pharynx which extended from the level of the short palate beyond the range of vision. This **retropharyngeal abscess** was incised and some of the pus inoculated into a guineapig. Seven weeks after the inoculation the animal was killed and the characteristic lesions of tuberculosis were found. The patient experienced immediate relief after the evacuation of the abscess and 5 months after the operation his throat was in good condition and his general health was excellent. This seems to be a case of tuberculous retropharyngeal lymphadenitis ending in suppuration. No point of entrance for the infection was found. [J.M.S.]

8. The Cerebral Neurons in Relation to Memory and Electricity. JAMES GRANT.
9. Report of Two Cases of Afebrile Typhoid. CHARLES J. WHALEN.

1.—McBride, in discussing the mental symptoms of **cerebral syphilis**, states that the mental derangement due to either remote or immediate syphilis may simulate every known form of mental disorder. In the majority of cases there is mental apathy and depression, a loss of self-control and general lowering of the mental process. He gives the history of a case exhibiting obscure early symptoms. He also reports another case illustrating mental weakness, incongruous delusions and loss of memory. He states that a common form of syphilitic insanity is characterized by long periods of confusion and dulness of memory, with sudden return of apparent sanity. He emphasizes the fact that insanity may occur soon after secondary syphilitic manifestations, and he cites a case in which it developed 6 months after infection. Recovery from syphilitic insanity hardly ever takes place for the reason that the repairing power of the brain is deficient. McBride holds the view that syphilitic disease corresponds to the following law: That the pathological changes are as a rule variable, irregular and diffuse. He further says that this law holds good in regard to the symptoms of syphilitic brain disease. Another variety of syphilitic insanity is characterized by delusions of personal injury, or persecution. Many individuals suffer from nervous syphilis and inebriety, so that it becomes difficult to give each its proper etiological significance. Another form of insanity is characterized by systematized delusions which continue for years, but later the disease shows confusion and gross brain-failure. He states that some cases of syphilitic insanity and parietic dementia are strikingly alike. Recovery from the former occasionally occurs while never from paresis. Cure (or recovery as implied in many other diseases) probably does not follow syphilis. The resisting powers of the individual are undermined. Brain disease is likely to develop in those who show bad hereditary tendencies. He believes that the intelligent and well educated are not so liable to insanity as the ignorant class. This, however, does not apply to syphilis, for both classes are attacked by the same poison, and as the resisting powers of the man of lower type are greater the poison therefore takes a weaker grasp upon his constitution. A definite diagnosis between syphilis of the membranes, of the cerebral arteries, and of the brain, is regarded by McBride as very difficult and often impossible. He lays great stress upon the fact that the entire natural history of insanity should be carefully investigated so that the whole course of the disease may be studied from the beginning, for the finding of the origin may aid in prevention. In conclusion he says that syphilitic insanity closely resembles the mental changes that occur in the senile. [F.J.K.]

2.—Hoppe says that the ill favor into which **operations for brain tumor** have fallen is due to the fact that so many operations have been performed for suspected brain tumor where sufficient means have not been taken for the purpose of definitely localizing the growth. He urges that operation for brain tumors and cysts should if possible be performed early. The fact that operations for such conditions have a high mortality should not deter us from advising operation when we consider that all cases of brain tumor are sure to be fatal. This is true even of the most benign growths, for they continue to grow and ultimately destroy the mental as well as the physical life of the patient. Improved results must come from the neurologists, not the surgeon, for early diagnosis and localization are points most to be improved. There is a great difference in the mortality rate of the cases operated upon where the tumor was definitely located and those in which its situation was uncertain. Hoppe quotes figures to prove this assertion. He reports seven cases of brain tumor coming under his care and operated upon by several different surgeons. He concludes with the following: (1) Tumors of the cortex or subcortical region which may be reached through the calvarium are operable; (2) if possible the operation should be performed early when the tumor is small; (3) brain surgery is limited to the psychomotor areas; (4) complete recovery seldom follows operation

for tumor. The focal symptoms and pain are relieved, but epilepsy and paralysis are seldom more than slightly diminished. It must be remembered, however, that the life of the patient has been saved; (5) because of the difficulty of localization and the small field for operation cerebellar tumors are inoperable; (6) the cumulative experience of all writers is against the exploratory operation; (7) the profession is divided as to the advisability of palliative operations; (8) he thinks that gummata when accurately located and diagnosed can be operated upon with success. Metastatic carcinomata are inoperable. [J.H.G.]

3.—Earles discusses the **anatomical relations** between the scalp, skull and brain, and urges a careful consideration and treatment of all injuries of the scalp and skull because of the damage which may have been done the brain, or which may result from infection of the wound. He then describes the technic to be followed in the care of such wounds. [J.H.G.]

4.—Peck, in discussing the **treatment of typhoid fever**, advocates the use of small doses of acetanilid in conjunction with the sponge-bath, or in some cases with the cold plunge. He also advises the use of chlorin as an intestinal antiseptic, purging with calomel and thorough washing of the lower bowel with sterilized water. Of 77 cases of typhoid fever treated upon this general plan, all of them recovered. [F.J.K.]

5.—Ullman reports a case of **influenza accompanied by 4 pneumonic attacks** with recovery. The patient's age was 23 months. The first attack was one of bronchopneumonia. On the eleventh day of the disease the temperature fell by crisis, only to rise again in 2 days with the physical signs of a consolidated left upper lobe. On the seventeenth day of the disease the temperature again fell by crisis. About 10 days later the right lower lobe revealed crepitant rales and signs of consolidation. This attack lasted until the thirty-fifth day following the initial attack. For 7 days after this attack the temperature remained normal. On the forty-second day, counting from the initial attack, the temperature rose, the pulse and respiration were frequent, and upon physical examination, bronchovesicular breathing and subcrepitant rales were heard in the left inter-scapular and mammary regions. He concludes the article by saying that the patient made a good recovery, and that one year has elapsed since the date of the illness. [F.J.K.]

6.—Packard found among 2,500 consecutive cases treated in the ear department of the Pennsylvania Hospital 7 in which the trouble was distinctly of **syphilitic origin**. He then gives a brief account of each case. He does not think that syphilis is a very frequent source of ear disease, and yet it is a complication, in a large number of dispensary patients, requiring treatment. Primary syphilis of the external ear is extremely rare. Bulkley, in an analysis of 9,058 extragenital chancres found 27 cases in which the sore was located on the external ear. Secondary and tertiary manifestations are met with much more frequently. Hereditary syphilis of the ear manifests itself most frequently in the middle and inner ear. Syphilitic disease of the middle ear originates usually from infection through the eustachian tube. Lesions of the internal ear occur very late in the course of syphilis. The symptoms of this condition are tinnitus and deafness coming on suddenly in either one or both ears, and not infrequently accompanied by unilateral facial palsy. Packard quotes very extensively from the literature on this subject. [J.H.G.]

7.—Woodward thinks that the **mastoid cells** are more involved in inflammatory conditions of the middle ear than is generally supposed; and because of the great danger of extension to the brain and its membranes, or to venous sinuses, he urges early operation in all cases when the antrum is involved in the inflammatory process. He discusses at length the following seven indications for the mastoid operation and illustrates his remarks with the report of a number of cases: 1. "Bulging of Shrapnel's membranes, with swelling at the inner extremity of the auditory canal." The usual treatment of incision of the drum is often not sufficient, and unless it gives efficient drainage the mastoid antrum should be opened at once. 2. "Persistent tenderness over the mastoid process." This is considered as indicative of the mastoid operation in both acute and chronic cases of otitis media. He thinks it a mistake to wait until suppuration is assured; he thinks the operation should be

done to prevent its formation. 3. "Swelling of the soft parts over the mastoid process." In suppurative otitis media, when this symptom presents itself, the radical should be done. The simple incision may cure a few cases, but is not enough. 4. "Granulations and fistulae in the external auditory canal." These are indicative of caries of the walls of the middle ear, and no treatment short of the mastoid operation will result in a cure of the condition. 5. "Persistent and relapsing fistulae behind the auricle." These conditions mean operation of a radical kind. The cases with relapsing fistulae are more apt to have brain complications than are those with persistent fistulae. 6. "Persistent and especially offensive otorrhea." These cases can only be cured by cleaning out thoroughly all the infective material. 7. "Sudden marked diminution, or absolute cessation is a symptom of great significance." It means the extension of the process. Operation should be done at once and the sigmoid sinus also explored. The operation as described by Macewen is recommended. The operation is done not for drainage but for the removal of diseased tissue. The dangers mentioned in connection with this operation the author thinks are greatly overestimated. He closes with a reference to diseases of the nose and throat as predisposing causes of suppurative diseases of the ear. [J.H.G.]

9.—Two cases of afebrile typhoid are reported by Whalen. He states that Liebermeister has called attention to afebrile typhoid. Whalen believes that enteric fever occurs in many different forms, and he wishes to call attention to 2 cases of afebrile typhoid, which he has observed. The first case he reports occurred in a male, aged 23, and the second case in a lad, aged 17. [F.J.K.]

6. Diagnosis of Leukemia from the Standpoint of the Blood-Changes. C. Y. WHITE.

1.—Charles W. Burr has given us a dignified and just tribute of the late Alfred Stillé, whose long life of 86 years, so full of professional activity and attainment, terminated on September of last year. Stillé was one of those young Americans who returned from his European studies under Louis, and others, whose zealous work did much to place modern medicine upon a basis of fact rather than theory. He was one of those who recognized the distinction between typhus and typhoid fever. The other American whose name is associated with Stillé's in this connection is that of George C. Shattuck, of Boston. Dr. Stillé was one of the founders of the American Medical Association, and its president in 1871. He was also an original member, and for three years, president of the Philadelphia Pathological Society. For many years he filled the chair of Practice of Medicine in the University of Pennsylvania. [T.L.C.]

2.—Ravenel and McCarthy have made a series of studies for the purpose of determining the rapid diagnosis of rabies. Up to the present time the only sure means of diagnosis in a vast majority of the cases has been the inoculation of rabbits from a portion of the nervous system of the animal inflicting the bite. The difficulties of this method are apparent, and the most important is the fact that from 2 to 6 weeks must elapse before the diagnosis can be made. Investigators have long endeavored to discover a shorter method for practical use, but it was Babes, in 1886, who first determined that the essential lesion of rabies consisted in an accumulation of embryonic cells in the neighborhood of the central canal, and especially about the large modified cells of the motor centers of the bulb and cord. Babes, in 1892, reaffirmed these observations and held that it was possible to make a rapid diagnosis of the disease by microscopic examination of the bulb and cord. He proposes the name "rabie tubercle" for the pericellular accumulations of embryonic

cells described by Kolesnikoff. Recently Nelis and Van Gehuchten discovered in the spinal ganglion of two men who had died of rabies and in a number of animals peculiar changes which they considered to be the diagnostic lesions of the disease. They hold that Babes has attached an undue importance to his rabie tubercle, and they believe that the earliest lesions are found in the peripheral cerebral and sympathetic ganglia, and the changes are especially marked in the intervertebral ganglion and in the plexiform ganglion of the pneumogastric nerve. The work of Ravenel and McCarthy leads them to adopt the views of Van Gehuchten and Nelis. They describe minutely the method employed in the 28 cases of rabies which they have examined. They report a case under the care of Dr. Krauss, in which a diagnosis of rabies was made and death resulted. Microscopic examination of the bulb and plexiform ganglia of rabbits inoculated from this patient showed the characteristic lesion. They lay stress upon the point that in dogs the changes in the cerebral, spinal and sympathetic ganglia are only specific of the natural or street rabies. Their conclusions are as follows: (1) When capsular and cellular changes in the intervertebral ganglia with accompanying clinical manifestations are present, they afford a rapid and trustworthy means of diagnosis of rabies. (2) When these changes are not present, however, we are not to conclude that rabies is not present. These lesions afford valuable contributory evidence. (3) In certain cases, when the capsular changes are slight, the changes are more marked in the distal-peripheral end of the ganglia. (4) That the rabie tubercle of Babes is present sufficiently often to prove of great value in those cases where only the central nervous system is obtainable without any of the ganglia, but in cases where these can be obtained they offer a simpler and easier method of diagnosis than do the brain and cord themselves. [T.L.C.]

3.—William G. Spiller advances the opinion from a considerable number of careful observations that lesions similar to, and possibly identical with, those of rabies may occur in other conditions. For instance, in the examination of the Gasserian ganglion in a case of endothelioma of this ganglion he found areas in which a proliferation of the endothelial cells of the capsule in the Gasserian ganglion with complete destruction of the nerve-cell body. While the diagnosis of rabies could not have been made in this case, Spiller became convinced that irritation or intoxication, or some other cause, such as a tumor, could produce a proliferation of the cells of the capsule about the nerve-cell body. In another case, one of Landry's paralysis, he found changes strikingly like those described as typical of rabies. He, therefore, concludes that no lesions are specific to rabies but under certain conditions, the findings may be of considerable importance in the diagnosis of rabies. [T.L.C.]

5.—Bergey has conducted a series of experiments with kalagua, a plant which was placed upon the market in 1898 as a specific remedy in the treatment of tuberculosis. A number of physicians have reported wonderful results from its use. He conducted five sets of experiments, three with guineapigs and two with rabbits. These animals having been inoculated with tuberculosis, were subsequently treated with kalagua. The most careful observation of the animals under treatment failed to reveal the slightest curative effect of the drug. On the contrary, the tuberculous animals which were untreated were the more thrifty. Accompanying the article are a series of tables showing the results of these experiments. [T.L.C.]

6.—C. Y. White discusses the blood picture in leukemia; the distinct types of this disease, the difficulties of diagnosis that may arise from certain known causes, and finally the value of the laboratory method in making the clinical diagnosis. Leukemia, from the microscopic standpoint, is divided into splenomyelogenous leukemia, lymphatic leukemia or lymphemia. The blood pictures in these 2 forms of disease are usually sharply defined, but in some cases one borders upon the other. Splenomyelogenous leukemia is characterized by the presence in the circulating blood of a progressive, pernicious anemia of secondary origin. The anemia being accompanied by all forms of red-cell degeneration, and by a leukocytosis, polymorphous in type and associated with the presence of foreign cells and leukocytic degenerations. On the other hand, lymphatic leukemia is associated with a less marked anemia and less

evidence of red-cell degeneration, by a less pronounced leukocytosis which is formed chiefly by an increase of lymphocytes and the less frequent presence of foreign cells. The difficulty of diagnosis of leukemia is greatly heightened when it is accompanied by an intercurrent disease. Two cases are cited from the literature showing the effects of intercurrent disease on leukemic subjects. In one there was a septic condition engrafted upon a leukemia of 3 years' standing; in the other a malignant tumor developed in the course of the case. From a clinical standpoint alone, cases of leukemia are often indistinguishable from **pseudo-leukemia, splenic anemia, chronic splenic tumors, enlarged glands and tumors of the left hypochondriac region.** It is the blood-changes which are usually characteristic, but not so in all cases; for treatment or the occurrence of intercurrent affections have frequently altered the blood picture. The necessity of carefully weighing all clinical data is important. [T.L.C.]

2. Experiences with the Medical Department of the Army in the South African War. JOHN CHIENE.
3. Address Delivered to the Edinburgh Obstetrical Society, at the Opening of its Sixty-second Session. MILNE R. MURRAY.
4. Operative Procedures for Simple Fractures which have been Unscientifically Treated. ARBUTHNOT W. LANE.

2.—Chiene gives a resumé of his **experiences in the South African war.** Many of his points are important and of practical interest. Every one must clearly differentiate between hospital trains and ordinary trains carrying invalids. In the former the soldiers were most comfortable; in the latter it was very often the reverse. The author is fully satisfied that in the future some form of portable cooking stove must be carried in these ordinary trains, by means of which simple food may be cooked for the soldiers. On a smooth road an ambulance cart is very comfortable; but, in the author's opinion, the McCormack-Brook ambulance litters are certainly more comfortable than ambulance carts, and he thinks it will be a question for future decision whether these litters shall not take the place of carts in the conveyance of patients from train to hospital. These litters are of greatest service for the removal of the wounded from the battlefield to the nearest hospital. Soldiers say they would rather travel in an ox wagon than in an ambulance cart. For anesthesia chloroform was the favorite drug. Ether and A. C. E. were in occasional use. Chiene never saw any trouble with any form of anesthetic. A little struggling, but no sickness at the time, and very little afterwards. Can the sickness in civil life be a nervous condition which does not hold good amongst soldiers in time of war? He is fully satisfied that the soldier accepts without demur any decision that is made in regard to his treatment. He is contented and asks no questions. "All right, I am ready," is his answer. The author is satisfied that the efficient use of the x-ray apparatus depends very much on the experience of the man who uses it. Another thing which was very evident in South Africa was the distinct division of patients into two great classes; those who were anxious to go home, and those who wished to go back and fight. The first were all septic cases, the second aseptic ones. Dysentery is the disease that most takes the heart out of a man. He was very anxious that his hearers should fully understand the great value of hospital trains and hospital ships. The wounds made by rifle balls at a range of between 200 and 400 yards were more ragged than those produced at a range of 1,000 to 1,500. The cases of head wounds must be divided into two groups: (1) Those in which the bone and brain are severely injured and torn; (2) those in which, with a comparatively small bone-wound, the brain is much torn. In the first the injury is probably, if no shrapnel is being fired, due to expanding or explosive bullets. In the second the Mauser bullet may be the cause when fired at a short range. The green-coated bullets were examined chemically by Marshall. Probably the cartridges were simply coated with suet or tallow for the purpose of lubricating the rifle barrel. In

course of time, the fatty acids originally present, and which would increase in quantity on keeping, have attacked the underlying metal, forming green-colored copper salts, which have gradually spread through towards the outer surface of the fatty material. From the point of view of those against whom the ammunition is employed, there can be little difference between such coated cartridges and those which have not been so treated; from one cause or another, the coating is fairly certain to be completely removed before the bullet reaches its billet. In Africa the majority of the cases of cerebral hernia that the author saw were on a fair way to recovery, and in some the recovery was complete. The antiseptic treatment can not fully account for it. Possibly it was the larger opening in the bone. Irvine, a civil surgeon, used solutions of formalin varying in strength from 5 to 25%. These solutions acted by drying up the mass and were, at the same time, antiseptic. Several cases of severe brain injury were followed by recovery. In several cases of arteriovenous aneurysm much improvement resulted from proximal ligation of the main artery, when the communication was between the carotid artery and the internal jugular vein. In the thigh, ligation of the femoral artery did good. In the leg, the aneurysm, as a rule, was laid open, and the artery and vein ligatured above and below the opening. The cases were more allied to aneurysmal varix than to varicose aneurysm, but there was not the great dilation of the vein that is commonly described in such cases. The absence of any venous dilation gave rise to the query as to whether the condition could be due to bruising of the artery and the vein, and subsequent matting with constriction. The number of cases of painful neuritis from bruising of nerves, the cases of neuritis due to adhesion of the nerves to bone after fracture, and the cases of neuritis due to splinters of bullets lodged in the nerve would lead one to suppose that possibly the same thing might have occurred to arteries and veins lying side by side, and by matting and constriction, produce symptoms similar to those met with when there is a communication between an artery and a vein. In lung injuries it was rare that the patient said that he spat blood at the time of the accident. On the other hand, it must be noted that in many cases there was hemothorax, probably from the intercostals, and most of the surgeons were agreed that if the blood was slowly absorbed, tapping assisted absorption, and there was also general agreement that a rise in temperature was the first indication that absorption had commenced. Empyema as a result of lung injuries rarely occurred. In all the cavities wounds which, from former experience, would have certainly proved fatal, were followed by recovery. The author saw several cases of penetrating wounds of the abdomen in which complete recovery had taken place without operation. There should be no delay in sending out the best incinerators, and compelling the authorities to burn the dejecta. The civil surgeons have been of much service in Africa. [J.M.S.]

4.—Lane, in discussing the **operative procedures for simple fractures** that have been unscientifically treated, calls attention to 2 classes of cases. In cases of the first class the prominent feature is the condition of mechanical disability which so often results from imperfect restoration of the broken bone to its normal form. The patient may require to be treated either for a more or less complete inability to perform his functions normally, or for pain, or for both conditions. The degree in which the above are present varies considerably with the displacement of the fragments and with the age and habits of the patients. They are generally very marked when they oblige the sufferer to submit to a serious operation which is surrounded with many risks and difficulties. The next class is that of nonunion between the displaced fragments, a so-called false-joint being developed at the seat of fracture. A very large number of these cases have come under the author's care, and have derived a varying amount of benefit from operative procedures, undertaken with the object of restoring the deformed bones as completely as possible to their original form. In the cases of the upper extremity the patient usually suffered from such a limitation of the movements of the bones on one another that he was altogether incapacitated from following his employment. Occasionally the radius and the ulna had united to one another. Sometimes also, in the case of a female patient, the very obvious deformity of the part, rather than the disability, induces her to undergo an

operation. In the lower extremity, pain, associated with a corresponding amount of mechanical disability, forces the sufferer to submit to an operation, however serious. The operative measures necessary to dissociate fragments that have become firmly ankylosed together, and perhaps to adjacent bones as well, and to saw off sufficient bone from each fragment in such planes as will restore the outline of the necessarily shortened bone, is often very difficult, and may be fraught with damage to important adjacent vessels and nerves. It seems little short of ridiculous to read the statements of surgeons that such mechanical disability is a rare sequence of fracture, and that it can usually be obviated by the use of massage and passive movements at an early date. That massage and passive movements serve to diminish the disability and pain that would otherwise ensue if these fractures are left for an indefinite period in rigid casing, is quite familiar, but such measures alone do not constitute sufficient treatment, and are merely adjunct. The second group of cases, namely, those of ununited or imperfectly united fractures, are due also to the same unscientific treatment of fractures. Lane has never come across one instance in which union would not have resulted if efficient operative measures had been adapted, and furthermore, he believes that ununited fracture is of comparatively common occurrence. Twenty case histories and 5 skiagraphs are given. [J.M.S.]

1. The Influence of Nutritive Enemata upon the Gastric Secretion. METZGER.
2. The Employment of Untwisted Strings of Reindeer Tendon for Stitches and Ligaments. SCHILLER.
3. Additional Contributions to the Bacteriology of the Chemical Disinfection of the Hands. ZAUFAL and SCHENK.
4. The Occurrence of Demodex Folliculorum in the Eyelid, and its Relation to Diseases of the Lid. HUNSCHKE.
5. The Relations of Oliver's Symptom to Aortic Aneurysm and Intrathoracic Tumor. JESSEN.
6. A Little Known Pupillary Reaction (The Orbicular Reflex of the Pupil) and its Therapeutic Application. KIRCHNER.

1.—Metzger has studied the effect of **nutritious enemata** upon the secretions of the stomach, in dogs and human beings. He found that by the employment of alkarnose he obtained positive results in 8 experiments, with free hydrochloric acid in the stomach-contents of 4. Simple enemata of water did not have this effect. He then undertook to study the effects of different enemata, and found that a mixture of bouillon and red wine was most certain to produce a secretion from the glands of the stomach. Having satisfied himself with these results in dogs, he undertook a series of experiments upon human being. After ordinary enemata it was found that there was sometimes a slight secretion of mucus which failed to give an acid reaction, or gave such a slight acid reaction that it could be disregarded. After, however, an injection of bouillon and red wine, there was a more abundant secretion, and also considerable free HCl. It seems to be difficult to explain these results, for there is no reason to believe that they indicate active resorption in the intestine itself. He gives a record of his cases. [J.S.]

2.—Schiller, although he believes that as a result of modern methods of preparation catgut can be adequately sterilized, and can be prevented from being absorbed too rapidly, nevertheless has made some investigations in order to determine whether it could not be replaced by fibrils from the tendons of various animals. He found that the ligamentum nuchae of the reindeer can be readily broken into fibers after brief maceration in water, and that these fibers are quite strong and long enough. They vary considerably in diameter, however. They can readily be rendered sterile by the ordinary methods employed for catgut, are very slowly absorbed, disappearing between the fifth and seventh week, and apparently have very little capillary action, so that they are not likely to conduct liquids deeply into the tissues. [J.S.]

3.—Schenk and Zaufal performed a series of experiments

upon their hands in order to determine the effect of various methods of rendering them aseptic. Vigorous washing with sand-soap was practically useless; after 30 minutes hard rubbing the enormous number of 122 colonies per square cm. could be counted, in fact the prolonged rubbing seemed to bring the microorganisms to the surface in even greater numbers. Even less satisfactory results were obtained by vigorous rubbing with a sterile brush and sterile soap. A series of experiments were also made with the mercurial ethylenediamine solution of Kroenig. This consists of 4 grams of ethylenediamine, 10 grams of citrate of mercury, and 86 grams of water. For the hands the solution can be diluted from 1 to 30 up to 1 to 200. Fragments of skin which had been previously washed with sand soap and then treated with this solution, were excised just before operation, and these remained perfectly sterile for long periods. The hands were almost invariably perfectly sterilized. Other solutions, however, such as bichlorid of mercury 1:1000, or oxidid of mercury, can also be employed with success. They conclude that the most perfect method of sterilizing the hands or skin is to wash the hands for 5 minutes with sand-soap, then 3 minutes emersion in one of the above mentioned chemical solutions, which should be as hot as can be borne. [J.S.]

4.—Hunsche has made a number of investigations upon the small hard sacs of the eye-lid in order to determine the presence of the demodex. He found that, omitting young children, in whom they are uncommon, they occur in 92½% of all cases. After the age of 40 they are invariably present. They are apparently in greater numbers in those cases which suffer from severe cachectic states. They do not apparently produce any disease at all, either of inflammatory or other nature. [J.S.]

5.—Jessen reports 2 cases in which the differential diagnosis between mediastinal tumor and aortic aneurysm was exceedingly difficult. The first case, a woman of 35, had had severe cough, difficulty in respiration and deglutition for about 2 months. Two days before admission to the hospital she had become hoarse. The pulse was equal on both sides; there was paralysis of the left recurrent nerve, but entire absence of tracheal tugging. The diagnosis of stenosis of the trachea was made, probably aneurysmal in nature, on account of the absence of signs of vascular disturbances. At the autopsy extreme atheroma of the aorta was discovered, with a sac-like dilation pressing upon the larynx. The second case, a woman of 45, had suffered from severe pain, difficulty in micturition, and rapid loss of power and weight. There was also severe pain in the rectum. There was slight fever, due to a cystitis, which was readily cured by appropriate treatment. She had a severe attack of pain followed by edema of the face, more pronounced on the left than on the right side. This was explained by thrombosis of the veins. There was a broad shadow just above the heart when the patient was examined with the fluoroscope, and there was distinct tracheal tugging both up and down, and to the right when the trachea was pulled toward the left. Further thrombosis occurred and the patient died. A diagnosis had been made of tumor in the thorax, producing pressure probably aneurysmal in nature. At the autopsy, however, a small round-cell sarcoma was found invading the right lung, pressing the aorta and forcing it firmly against the trachea and esophagus. Jessen therefore thinks that neither Oliver's symptom nor Cardarelli's sign are pathognomonic for aneurysm; nor do they necessarily occur in all cases of aneurysm of the thoracic aorta. [J.S.]

6.—Kirchner gives a careful analysis of the pupillary phenomena described by Gallassi, Westphal, and especially by Piltz, and mentions a few of the positive results obtained from these studies. It is probable that focal lesions will be definitely localized when, in the presence of paralysis of the facial nerve or of the muscles of the bulb, this reaction fails. He believes that the reflex passes along certain tracts in the posterior longitudinal bundle. It is difficult to say how frequently it occurs, and it is not certain that it is ever purely unilateral. He advises physicians to carry out investigations of reflex systematically. [J.S.]

10. The Occurrence of Rhodan in the Nasal Secretion. A. KELLER.

1.—Craemer considers one of the first principles of the obstetrician is not only to bring the child living into the world, but also to keep it alive; hence a study of the development and nourishment of the newborn belongs to his specialty. Quetelet, in 1835, first gave the normal curve of development in the newborn child. This characteristic weight curve shows that in the first 3 or 4 days the nourishment taken does not compensate for the loss by sensible and insensible excretion, and there is a loss in weight of 220 to 250 g. which is regained by the tenth day. This loss of weight is not to be considered as a disadvantage to be avoided by abundant artificial nourishment, but as normal. The child really needs but little nourishment during the first 48 hours, and may do without any and suffer no injury. On the other hand, at this time care is needed in the proper nourishment of the mother, beginning with nutritious, easily-digested fluids. We must rest in the position that the healthy woman will furnish milk adapted to the infant. Yet there are numerous examples in which irregularity in rest or care of the child or overabundant feeding has produced bad results. If, however, there is a failure of natural nourishment for the newborn infant, Craemer agrees with the opinion of Biedert that it is important in the artificial feeding of infants that the measure of nourishment should be the smallest possible; that this principle is based upon abundant experience. He thinks, however, that experiments in this direction should be made in carefully conducted hospitals. [W.K.]

2.—Dammer reports a case of **tetany** in a woman, 35 years old, in whose stools segments of *taenia medicanelata* were found. She was given extract of *felix mas* and calomel, followed by the expulsion of the worm entire, with the head attached. She was very weak afterward, and had an attack which began with a "creeping" in the arms and legs, followed by unconsciousness. On regaining consciousness, both upper and lower extremities were stiff. She perspired, had tinnitus aurium, and visual disturbances during the attack. Her hands were blue and cold. The attack lasted about 5 minutes. Other attacks occurred, described by her physician as typical tetany. Both Trousseau's and Chvostek's signs were present. She recovered in three weeks. As no other cause for the attack could be found, Dammer concludes that it was due to the extract of *felix mas*, the calomel, or both. The literature of the subject is given. [M.O.]

3.—Zorn reports a case of a man of 41, who by mistake had swallowed 30 ccm. of **formalin**. He had dyspnea, vertigo, nausea, vomiting, and a feeling of burning in his mouth and stomach. The odor of formalin was still present and his stomach was immediately washed out. There was slight cyanosis. Absolute anuria persisted for 24 hours, the bladder remaining empty. The bowels were loose, with much mucus. The urine passed later contained albumin and casts. His pulse was small and rapid. Examination of the glass which had contained the poison, revealed formaldehyde. He recovered in a week. [M.O.]

4.—After a full review of the literature upon the subject, Schanz states that a **plaster jacket** should only be applied in **scoliosis** after attempts to improve the existing condition have been made by all the other known methods. [M.O.]

5.—Marx believes that **intubation** possesses most of the advantages of tracheotomy and is an easier procedure, needing no assistants is quickly done, and as there is no open wound extension, preparation is unnecessary. Complications are less likely to occur. After the tube has been introduced it requires careful attention, and must be kept clean. A point that has been held against intubation is the liability of the tube to be coughed up, or pulled out by the string that is intended

to keep the child from swallowing it. Should this accident occur the tube can be easily reintroduced with but very little inconvenience. Its use is more general than usually supposed, and it may be used in any constriction of the larynx. [W.S.N.]

6.—Avellis reports a condition common to adults who are otherwise well, yet complain of severe pain upon swallowing or talking loudly. It occasionally disappears for days, only to return again. The pain was unilateral, occasionally bilateral, and never occurred in neurotic individuals. There were no other symptoms. Examination failed to elicit anything abnormal, either inside or outside. These cases are more frequent in spring and summer, and all treatment seems useless. Avellis came to the diagnosis of **neuralgia of the larynx** by finding that the superior laryngeal nerve, at its outlet in the thyrohyoid membrane, was very sensitive to pressure. Another painful point was in the sinus pyriformis, where the nerve lies very superficially. Treatment with the antineuralgics, phenacetin, etc., and with warm applications cured the condition at once. Avellis gives the differential diagnosis between this condition and the ailments which might be confused with it, rheumatism of the cervical muscles, lateral bursitis, and hysteria. He also reviews the meager literature upon the subject. [M.O.]

7.—Hoefmayr details the various **cardiac manifestations of neurasthenia**. The main condition to be relieved immediately in the pseudocardiac attacks is constipation. In all cases the bowels must be kept regular. Another common symptom, the pressure headache, can be best treated by daily cold bathing, which causes the blood to leave the hyperemic cerebrum and to spread through the peripheral vessels. He reports 3 cases in which opium, with attention to the bowels, brought about prompt recovery. [M.O.]

8.—Jochner in an article on surgery tells of 2 cases, the first a cut in the forearm, completely dividing the extensor communis digitorum. Erysipelas followed, and when the wound healed there was considerable separation of the muscle tissue. After all inflammation had subsided the ends of the muscle were brought together with silk sutures and perfect union followed; although the arm was stiff for some time, massage and electricity restored it to its normal condition. The second, a case of obstruction of the bowel with an operation for relief (artificial anus), a carcinoma being found to involve the sigmoid flexure. This was followed by a second operation in which he removed the carcinoma and brought the bowel together with a Murphy button; that night the patient had a large natural action of the bowel. Jochner fully expected some complication to follow, but none arose, and the button was passed about 4 weeks later. When the patient had sufficiently recovered a third operation was performed to close the artificial anus. [W.S.N.]

9.—Paulsen mentions as causes of **umbilical hemorrhage** 3 different conditions: Acute fatty degeneration in the newborn, regarding which there is complete darkness; congenital syphilis; and general sepsis. Finally, there are rare cases of umbilical hemorrhage in children afflicted with hemophilia. Grandider estimates that out of 223 cases under his observation, 14 were due to hemophilia. Paulsen was called to a 9-day-old child suffering from umbilical hemorrhage. Tamponing and compression by bandages having failed to check the bleeding, he thought to try suturing; but the flow of blood from the stitch canal which coagulated with difficulty, convinced him that it was a case of hemophilia and he was compelled to abandon the attempt. The child died soon after, the death being apparently hastened by internal hemorrhage. A large hematoma was visible under the mucous membrane of the rectum. The hemorrhage was undoubtedly spontaneous, since the child was found with the blood flowing while in a restful sleep. From his own experience and also that of other physicians, Paulsen thinks there is nothing to hope for from surgical treatment of such cases. He wished to try gelatin injection, but the rapid approach of death prevented and the experiment remains to be made in the future. [W.K.]

10.—Keller mentions the fact, discovered by him, that **rhodan is present in the nasal secretion**, and not in the saliva, of children 2 and 3 months old. He used paper colored yellow by a hydrochloric acid solution of chlorid of iron, which was turned red by the rhodan. [M.O.]

8. Antisepsis and Asepsis in Antiquity. MARCUSE.

1.—After commenting on the two main theories in Darwin's "Origin of Species," that of "descent" and that of "natural selection," Schwalbe seeks to show evidence of both in bacteriology. He reviews the subject from the beginning, explaining in detail the pleomorphism of bacteria, taking the tubercle bacillus as an example. **Tubercle bacilli in mammals and in birds are but varieties of the same species.** Finally, Neumann's experiments with staphylococci prove that many varieties may exist, each forming colonies of a different color. It seems more than probable, though by no means proved, that the theory of natural selection exists even here. Thus, according to Schwalbe, both of Darwin's main ideas prevail among bacteria, just as they do among the other living species. [M.O.]

2.—Rosenbach calls attention to the variability of the caliber of the temporal artery in various conditions such as migraine, muscular exertion, neurasthenia, etc. He has also observed that after the instillation of a 1% solution of cocaine into the eye the temporal artery on the same side becomes at first slightly larger and pulsates more vigorously, then when the anemia of the conjunctiva is complete, it is about normal in size, and as the subsequent hyperemia appears, gradually decreases. This decrease is quite persistent, being present for at least one hour after the anemia, when the conjunctiva was about normal in appearance. As the vessel became smaller it was observed that its wall became slightly more rigid. In a few cases the artery contracted before anemia appeared in the conjunctiva. This phenomenon, however, was apparently observed only in 2 of a number of cases, although Rosenbach insists that exceptional instances are of the greatest value in the elucidation of obscure pathologic facts. [J.S.]

3.—Dieters reports two cases of typhoid fever in adults, in both of which a stage of initial delirium existed before the fever appeared. They were sister and brother. The father was an imbecile; the mother and a brother had been insane. The man, aged 25, had never shown much intellect. He was maniacal for two days without fever, growing calmer when the fever appeared. The Widal reaction was positive, and he recovered. His sister, aged 17, was maniacal for 3 weeks. Then she developed fever, and albuminuria, and became very weak. She died suddenly. Autopsy showed typical typhoid lesions in the intestines. Dieters calls attention to the fact that, in all such cases, typhoid should be suspected. He does not wholly agree with Audemard, who thinks that such cases may exist without ever showing any signs of typhoid. [M.O.]

4.—Port has carefully studied the vertebrae in chronic scoliosis and has found that the curvature of the vertebral column is due in the large majority of cases to an abnormality in the growth of the vertebra, or rather that on account of the unequal loading of the spine the deformity occurs. As a result he does not believe that there is any possible cure after the epiphyseal cartilages have ceased growing, and that hope for cure only exists during early childhood, and that the prognosis becomes progressively worse with advancing years. He therefore thinks it is desirable not to undertake treatment, because, if the muscles on the concave side are stretched and weakened by apparatus, and the treatment is interrupted before their strength is restored by gymnastics the resulting scoliosis will be worse than before. [M.O.]

5.—On account of the absolute want of good milk, the mortality from diarrhea with vomiting, among infants

under 1 year, in Worms is the highest in all Germany. Gernsheim treated such cases with gastric lavage and enterocolysis. After purging with calomel, he gave a cream mixture (1 part cream and 20 parts water) to infants under 6 months old. To older infants he gave a mixture of oat meal gruel and milk (4 parts gruel and 1 part milk). Of 37 cases only 1 died. His youngest patient was 12 days old and she is now quite well. [M.O.]

6.—Lublinski believes that there is close connection between pachyderma laryngis and leukoplakia oris, both depending upon the abnormal tendency on the part of the epithelium to undergo cornification. He uses in the treatment of both a solution of salicylic acid in alcohol, with moderate success. On account of the difficulty of application and the continual irritation of the vocal cords, cure is uncommon, and recurrence almost the rule in the larynx. [J.S.]

7.—Breitung reports the case of a boy 3 years of age, who placed a horn button in the right nasal cavity. This was pushed further into the nose by the clumsy efforts of a local physician, and finally was only removed by the combined effects of the forceps and the method of Seibert, that is, vigorous reverse blowing with the Politzer bellows. [J.S.]

8.—Marcuse mentions the various methods employed by Moses, Hippocrates and others for the prevention of the spread of contagious diseases, and mentions particularly the directions of Anagnostakis, who advises clean dressings and water so warm that it can barely be borne. [J.S.]

1.—Hoffmann describes a third type of hereditary muscular atrophy, spinal in origin, occurring in early infancy. He distinguishes it from the two main classes, pseudohypertrophic muscular atrophy (Erb and Duchenne), and progressive neurotic muscular atrophy (Charcot Marie). It begins between the fifth and ninth month, in children of healthy parents, hitherto well, born without instruments. In the weeks following, the child moves the legs at the hip joint gradually less and less. Soon, then, a symmetrical weakness is noted in the muscles of the back and abdomen, so that the child can with difficulty sit up. As months pass, the shoulders and neck also become affected, and the legs, further down, first with weakness, then paralysis. Finally, arms and hands are paralyzed, and the reflexes disappear. The organs of the special senses and the cranial nerves (except the twelfth) are not affected. The paralysis is flaccid, atrophic, followed later by kyphoscoliosis, contractures, etc. The prognosis is fatal, death occurring from 1 to 4 years after the disease began. Autopsy shows symmetrical degeneration of the peripheral neurons of all the nerves leaving the brain below the hypoglossal, and widespread severe muscular atrophy. The brain is normal; there are no bulbar symptoms. The literature of the subject follows. [M.O.]

3.—From an examination of 300 bodies brought in as suicides, Heller collects these facts: The majority were between 20 and 60 years old; more men than women; the majority hanged or drowned themselves; comparatively few men took poison (that most used was potassium cyanid), while a number of women took phosphorus. The suicides occurred mostly in the spring months. Twenty-four percent

had acute diseases; 47% were alcoholic; 47% of the women were menstruating or pregnant; in all, 43% were not accountable for their actions. He ends with a discussion of the German laws upon suicide. [M.O.]

5.—von Dungern's method of making cow's milk more digestible is to heat the milk to the temperature of the body, and to cause clot formation by the addition of **lab-ferment**, added, as a rule, with the milk sugar. This is then shaken up, so that only very fine, easily-digestible clots remain. [M.O.]

6.—Kopp has found that protargol-glycerin solution, applied early, will **abort** most cases of **gonorrhea**, and dwells upon personal hygiene as a **prophylactic** measure. [W.S.N.]

7.—Sagebiel has employed **naphthalan**, a peculiar form of raw naphtha, in cases of **eczema**. Five patients suffering from chronic eczema gave excellent results in 4, and distinctly bad results in 1. In 35 other cases with acute eczema the results were satisfactory in 32, and unfavorable in 3. This substance has the consistency of a salve, and is applied directly without previous preparation of the surface, such as the removal of crusts, etc. Then a bandage is applied and changed once in 24 hours, with renewed applications of the drug. In all the favorable cases desquamation occurred quickly, and without reaction, and a complete cure was obtained in an interval of from 2 days to 3 weeks. In the 4 unfavorable cases there was a pronounced inflammatory condition with redness and swelling. [J.S.]

8.—Holz reports the case of a man, 42 years of age, who was suddenly attacked with colic-like pains in the abdomen followed by gradually increasing meteorism, difficulty in breathing, and apparently complete obstruction of the bowels. The patient was treated with opium and enemata, the latter sometimes of enormous size, but utterly without results. Finally, on the fourth day $\frac{1}{16}$ grain of atropin was injected hypodermatically. The following day there was expulsion of considerable flatus, followed by a firm movement, and the patient rapidly recovered. [J.S.]

9.—Demme reports 2 cases of **intestinal obstruction** where he injected 0.005 gram (about $\frac{1}{16}$ grain) of **atropin** into the abdominal wall and in a few hours afterwards the bowels operated freely. [W.S.N.]

10.—Luttgen reports a case of **obstruction** of the bowel occurring in an anemic woman 65 years of age, who for years had suffered from an uncontrollable femoral hernia. Large doses of castor oil and jalap, etc., as well as injections, were given without relief. It then looked as if the hernia was the cause of the trouble, but operation proved the bowel here to be normal. The day after operating a solution containing 0.005 gram (about $\frac{1}{16}$ grain) atropin sulfate was injected into the abdominal wall, this caused severe symptoms of atropin poisoning and also considerable reaction, but in about 12 hours the bowels operated and the case then progressed favorably. [W.S.N.]

11.—Erne reports great success in disinfecting with the **carboformal hot blocks**.

12.—A history of Erb's life and works, in celebration of his sixtieth birthday.

8. The Justification of the Doctrine of Self Infection in Obstetrics. FEHLING.
9. The Artificial Nourishment of Infants. SOXHLET.

1.—It is obvious that the resistance that is exerted to the movement of a fluid in a system of tubes depends upon 2 facts; first, the caliber of the tubes, and second, the internal friction of the liquid, or its viscosity. It is not reasonable to

suppose, therefore, that all cases of increased resistance in the human blood are due to arterial sclerosis, and it seems likely that possibly in nephritis the increased work of the heart may be due to some alteration in the composition of the blood. The object of Hirsch and Beck was to discover some method by which the amount of resistance due to the condition of the blood could be measured. They adopted in general the method of Hurtle, and working with human blood found that in the same individual the variations in the time required for a given quantity of blood to pass through the capillary apparatus was not more than $\frac{1}{4}$ of a second, whereas between different persons suffering from different pathological conditions the variation was between 26 and 82 seconds. The essential feature of the apparatus is that the blood is forced through a capillary tube of known size, by constant pressure; the period required for the blood to pass through this tube indicates its viscosity. The reckoning of the viscosity, however, is accomplished by means of a complicated formula and is compared with the viscosity of water, at the same temperature, that is 38° C. The present communication is preliminary, and the authors merely state that in more than 100 experiments upon unchanged human blood they found that the results agreed with the law of Poiseuille, and corresponded closely with those of Hurtle upon animal blood. [J.S.]

2.—Starck, in the study of **esophageal tumors**, finds that the **diverticulum** sound meets the requirements better than all others. It acts as a pathfinder, in cases of malignant tumors where the surface is very uneven, with many pockets, the exact width of the canal can be determined; the location of the tumor can easily be made out and its lower border reached; and the stomach and contents can be studied. Besides it is of use therapeutically, for by passing it through the constricted portion, food can be placed in the stomach, or the stenosis may be dilated, and if any irregularities in the canal exist they will also be straightened. [W.S.N.]

3.—Klebs details a series of experiments made upon white rats, concluding that the ability to withstand tubercle-toxin bears no relation to the weight of the individual, that tubercle-toxin may act cumulatively; and that tuberculocidin will raise the temperature that the tubercle toxin had lowered. Its action decreases in power when given in repeated doses. Therefore all tubercle-toxin must be well removed before thinking of **treatment with specific extracts from cultures of tubercle-bacilli**. He reports a case to illustrate this. Then follow cases which were treated with tuberculocidin, in all of which the tuberculosis became latent. Success by this treatment can only be expected in those morbid processes which were produced directly by the tubercle bacilli. Tuberculocidin may be given by the mouth, by hypodermic injections, and by applications directly to open wounds. Klebs reports a surgical case in which it was successfully used. [M.O.]

4.—Braatz gives the following reasons why **alcohol** is valuable for **disinfecting** the hands: (1) Alcohol absorbs the air held in the pores of the skin; (2) before a liquid can reach the skin behind this air it must be absorbed; and (3) alcohol dissolves about 10 times more air than water, thereby reaching the germs better than any antiseptic dissolved in the latter. [W.S.N.]

5.—Sagebiel has employed **amyloform** in the **treatment of purulent otitis** of the middle ear, and concludes that it is of little value. It is composed of 96% starch and 4% formaldehyd, and the starch being insoluble, forms in lumps; he therefore prefers some powder easily dissolved, such as boric acid or xeroform. [W.S.N.]

6.—Hügel reports a case of **pityriasis rubra pilaris** in a laborer, 72 years old, who was perfectly well up to 2 years ago. Then he had cancer of the lower lip, which was extirpated. Just a year ago he noticed a slight itching in the extremities, which gradually spread over the entire body. His body was covered with thick, shiny, scaling papules, never confluent, and the extremities showed wrinkles and fissures. About each hair follicle was a raised epidermic mass, looking like "goose-flesh." Under the scales the epidermis was red and hyperemic. Arsenic, given subcutaneously, was stopped on account of diarrhea. Boric ointment was used externally. [M.O.]

7.—Ostermaier reports a case of **biliary colic** due to gallstones, in which the symptoms were relieved by a hypoder-

mic injection of $\frac{1}{2}$ grain of atropin; and of a man, 80 years of age, that had been absolutely constipated for 10 days, and was profoundly collapsed, who was greatly improved by a hypodermic injection of $\frac{1}{2}$ grain of atropin. This was repeated, and finally, on the fifteenth day, there was a copious evacuation of feces. The patient recovered completely. He believes that in such cases the effect of atropin is exceedingly satisfactory. [J.S.]

8.—Fehling, who does not accept Ahlfeld's theory of self-infection, thinks that the name is often incorrectly applied to cases in which the infection arises externally. His reasons are: (1) That absolute disinfection of the hands is today impossible; (2) that there appear in the genital tract of pregnant women saprophytic microbes closely resembling and easily mistaken for pyogenic bacteria, yet not usually the cause of infection; (3) that it is possible, during the puerperium, for bacteria to enter the vagina and even the uterus from the external genitalia, following injuries to the vulva. He then gives the experience and statistics of many obstetricians, by whom his views are confirmed. He says that the great advance in the prophylaxis and treatment of puerperal fever is only since Lister. Bacteriological examinations during the last ten years have shown us how complex the condition is. Further advance and additional light can only be gained when bacteriologic and clinical examinations keep together hand-in-hand. When positive knowledge has been obtained concerning the above-mentioned premises, the question of self infection may be definitely decided. [M.O.]

9.—After reviewing the experiments done to find the cause of scurvy and rickets, Soxhlet shows that cow's milk, though containing about twice as much sodium chlorid as human milk, is yet too poor in salt to satisfy the increased demands made by it upon the hydrochloric acid production of the stomach. The old practice of adding a pinch of salt to cow's milk when preparing an infant's food, is thus proved to be reasonable. Then he details the experiments of Zweifel, which show that sterilized milk is easier digested than uncooked milk. He quotes many passages, where sterilized cow's milk was used to cure rachitis and scurvy, and ends by advising the home modification and sterilization of milk mixtures by the mother. [M.O.]

8. Results of Vaccination in the Kingdom of Bavaria in 1899. STUMPF.

5.—Kaufmann gives a very interesting account of a small epidemic of smallpox that occurred in Frankfort among some strikers and the prisoners in a jail. The course of the infection after some very painstaking inquiries, was finally clearly made out, and it was found that every case practically was the result of direct contact, with one exception, and in this it was necessary to assume that in some cases smallpox runs its course without the typical vesicular eruption. The source from which the disease was imported into the city could not be determined. Altogether there were 26 cases. Although the two attending physicians were not restricted in their actions in any way, they did not communicate the disease to any others. Both visited the patients in linen garments, and immediately after the visit bathed and made a complete change of clothing. The relation of the severity of the cases to vaccination is interesting. In one case vaccination had occurred within a period of 6 years although it had not been successful. This case was exceed-

ingly light. Five other patients had been vaccinated within a period of 20 years, and had exceedingly mild attacks; 13 patients had been vaccinated within a period of 20 to 50 years before the attack; 5 had the disease in a mild form, 5 in a moderately severe form, and 3 in a very severe form; 5 cases had not been vaccinated within a period of 50 years; 2 had the disease in a severe form, and 3 not in a very severe form. It, therefore, seems to be proven by this epidemic, as in many others, that the protective influence of vaccination very gradually decreases. Seven of the cases were vaccinated during the attack, 2 for the first time, and in 4 the vaccination was successful. The preliminary exanthema was sometimes extensive, sometimes restricted to two or three small spots. When it appeared in the mildest cases, the patients felt perfectly well, and one of them refused to believe that he had smallpox. In the more severe cases there was fever and the characteristic pains. The initial fever was not observed. The secondary fever showed three types, that is to say, the moderate and mild type remained afebrile, or there was an irregular fever of mild degree, lasting for several days. Two cases had the typical hectic fever. In 2 cases the exanthema appeared whilst the initial fever was still high. Two cases were observed in which an eruption occurred during the initial fever. In one this was hemorrhagic in type, in the other roseolar. Sequelae were not serious; 4 cases suffered from furunculosis and 4 from seborrheic eczema. Four of the cases died. One was brought to the hospital in a comatose condition, another died during suppuration, a third at the height of the disease, and a fourth was an old man of 77. [J.S.]

6.—Hügel reports a case of lichen obtusus occurring in a woman of 37, having lasted for 3 years. Small papules appeared on the backs of the hands and feet. The patient suffered from severe itching; gradually the papules spread to the legs and forearms. These papules were discrete, about 4 to 6 mm. in diameter, and 2 to 4 mm. elevated above the surface of the skin. There was a slight depression in the center of each. The old ones did not disappear. The central depression corresponded to a sweat pore. Pathologically they consisted of enormous proliferations of the connective tissue of the skin, which actually caused atrophy of the papillae. It produced no general symptoms. He also reports a case of pityriasis rubra pilaris in a laborer 72 years of age. At the age of 71 he noticed some itching in the limbs and moderate desquamation. Gradually the movements of the legs became imperfect, the skin became thicker and shinier, and there was considerable desquamation. Gradually the whole surface was involved. As a result of treatment by arsenic and baths he gradually improved, but finally died as the result of a severe bronchitis. At the autopsy an area of softening was found in the right parietal lobe, and, in the skin, marked hypertrophy of the epidermis, with inflammatory reaction around the papillary bodies. [J.S.]

7.—Model reports his own case. As a result of almost total agrypnia he had recourse to chloral, and noticed whilst using this that after severe exertion he had a profuse hemorrhage from the nose. On several subsequent occasions this same manifestation occurred, and he was finally compelled to believe that the epistaxis was due exclusively to the use of chloral, because it never occurred unless the chloral was used, and always occurred when it was. He reports the case for the purpose of calling the attention of the medical profession to this danger. [J.S.]

8.—Stumpf gives some elaborate statistics of the results of vaccination in the kingdom of Bavaria during 1899. The total population in 1895 was nearly 6,000,000. In 1899 it was found that about 200,000 required inoculation. Altogether about 170,000 were actually inoculated, the greater number with glycerin lymph obtained from calves. About 128,000 required reinoculation and 125,000 were actually inoculated, nearly all with good results. He calls attention to the enormous production of lymph that is required to inoculate this number of people. Nevertheless, 63 calves were sufficient to supply over 400,000 portions in the year 1899. This lymph was of high degree of virulence, and preserved its potency for a long time. The lymph supplied by the Central Vaccine Institute of the kingdom of Bavaria proved to be more effective than that from other sources. In performing the inoculation, sterile instruments were always used; the best sterilizing medium being, apparently, alcohol. A very excellent instrument is a lancet of platin-

iridium; that, of course, can be sterilized by direct heat. [J.S.]

1. Experience with Angiotripsy. WINTERNITZ.
2. Intra-Tendinous Ganglia. MORIAN.
3. The Determination of the Time of Certain Appearances in Corpses. WETZEL.
4. Tropon and Plasmon. MÜLLER.
5. Contributions to the Knowledge of the Traumatic Mobility of the Kidneys. PAYR.

1.—Winternitz, stimulated by the apparently good results of various operators with angiotripsy has collected the statistics from Dölerlein's clinic of the cases in which this method was employed. They amounted to 150, consisting of 96 laparotomies, 52 total extirpations, 1 vaginal ovariectomy, and 1 nephrectomy. Four cases died, 2 from indifferent causes, and 2 from peritonitis as the result of a secondary hemorrhage after total extirpation for myoma. None of the instruments employed, that is, those of Doven, Tuffier, and Thumim, were satisfactory in all cases, and in consequence of the bad results in 2 cases, Winternitz believes that angiotripsy will not replace ligatures or clamps. [J.S.]

2.—Morian reports a case in which swelling took place in the tendons of the hand, accompanied by great pain, and interference of the movements of the fingers. At the operation it was found that both the extensor tendons of the index finger were swollen and contained small cysts, from which a colloid substance was evacuated. [J.S.]

3.—Wetzel calls attention to the errors in the features suggested by Casper for the recognition of the period for which a body has been kept after death, before the examination. These are briefly, that the body becomes cold in from 8 to 12 hours; postmortem discoloration appears in from 3 to 6 hours; rigor mortis in from 2 to 4 hours. The eyeball becomes soft in 2 or 3 days; the muscles become flat; the abdominal wall becomes green, and the peculiar, characteristic odor appears in from 2 to 3 weeks. For longer periods the following characteristics are suggested: The back becomes green, and froth appears in the nose and mouth in from 3 to 5 days; the whole body becomes greenish-red, and intensely distended, and there is collapse of the cornea in from 14 to 20 days; the cellular tissue becomes emphysematous, the entire body is swollen out of shape, and the nails fall off in from 14 to 20 days. Putrid liquefaction, rupture of the normal body cavities, loss of the eyeballs, and even exposure of the bones occurs in from 4 to 6 months. These rules apply only to bodies that have been left in the air. In the winter-time bodies will remain almost unchanged in water for considerable time. Wetzel, as the result of his experience as Judicial Medical Examiner for a large district in Germany, believes that these rules are by no means fixed, and that as a matter of fact it is necessary to individualize each case presented for examination, for, as is well known, temperature and other modifying conditions have the greatest effect upon the state of the body. He mentions a case of a man who drowned himself, whose face, after 3 days in the water, became completely unrecognizable on account of swelling and discoloration. In another case the color of the skin was black or dark green, the hair, epidermis, and the nails had loosened or fallen off; the odor resembled that of a pestilence; the liquid brain burst through the skull upon an attempt to open the cranial cavity, and yet the body, after 2 days in the air, had remained only 2 weeks in the water. Also, an autopsy upon 2 newborn children, in which the one with more advanced changes in the lungs had been buried for 3 weeks, after lying 2 days on its mother's bed. The other had been killed and thrown in the water, where it had remained for 4 weeks. He then calls attention to certain important features that he believes of as much value as those suggested by Casper. These are the effects of various of the lower animals that destroy bodies. For instance, rats have been known to completely remove all the soft parts from a child's legs in 4 hours. Maggots have almost completely eaten the soft parts of a body in 16 days, and in 2 days they have left nothing but the skeleton of a child. On the other hand, cases may be excellently preserved for long periods, particularly if carefully buried in the winter-time, and Wetzel has performed a perfectly satisfactory autopsy 4 months after

death. Decomposition proceeds with varying degrees of rapidity. In an autopsy upon a newborn child, although the soft parts had disappeared, the bones at the end of 4 months were still in parts attached together, and it was possible to determine that the age of the child was between 32 and 36 weeks. In another case it was impossible to determine the time in which the body had been kept after death, only a few bones remaining; but this was due to the fact that it had been exposed to chickens who had probably eaten the maggots from it, and contributed to its disintegration. [J.S.]

4.—Müller has performed a series of experiments with artificial preparations of albumen. He has used dogs, and carefully determined the nitrogenous intake and loss. It was found that in a preliminary period in which meat and dog biscuit were employed there was a slight excess of ingestion over excretion, but that there was considerable variation from day to day. During the tropon period, which lasted 38 days, there was a considerable increase, and the same was true during the terminal period, although the body-weight of the dogs decreased considerably. It appears from a careful analysis of the results, that about 93% of the nitrogen in meat was utilized, and only 83% of that in the tropon. [J.S.]

Berliner klinische Wochenschrift.

December 3, 1901. [37. Jahrg., No. 49.]

1. Diabetes Mellitus. C. v. NOORDEN.
2. Diffuse and Chronic Edema of the Skin with Laryngeal Involvement. W. LUBLINSKI.
3. Results in the Treatment of Sporadic Cretinism with Thyroid Extract. H. NEUMANN.
4. Treatment of Fractures of the Jaw. WARNEKES.
5. The Treatment of Nervous Diseases in the Family. R. GNATKE.

1.—The author's contribution deals with the current investigations of diabetes mellitus. The extensive increase in the number of cases of diabetes mellitus raises the question as to whether this is due to improved methods of examination, or to an increase of the disease. The most recently advanced etiological factors are chronic alcoholism, heredity, and racial predisposition. The author believes that the intermarriage of the Hebrew race with Indogermanic races plays an important part in the dissemination of diabetes. The supporters of the theory that the formation of sugar arises from fat, are increasing. The elimination of substances containing no nitrogen, and derived from the fatty acid series (acetone, B-oxybutyric acid), according to the investigations of Naunyn are derived from the B-oxybutyric acid. The origin of this acid is still disputed. The most recent opinions point to its derivation from the higher fatty acids. It is still a question as to whether the production of this substance during coma bears any causal relation to the latter, or whether both are dependent upon one and the same cause. [M.R.D.]

2.—Lublinki reports a case of diffuse chronic edema of the skin involving the larynx, occurring in an otherwise healthy woman of 52. The edema spread over the breast, neck and head, originally starting from the face. There were respiratory difficulties and the disturbances of phonation were due to swelling of the epiglottis, arytenoid cartilages and of the arytenoepiglottic and interarytenoid folds. The author has frequently seen cases of nephritis in which the edema manifested itself in the epiglottis and around the larynx before edema of the external portions of the body could be seen. But in this case, with absence of headache, polyuria, cardiac symptoms and intraocular changes, he believes himself justified in making the diagnosis given in the title of his paper, at the same time duly considering the previous occurrences of similar affections. The edema involving the mucous membrane gradually subsided under the administration of arsenic and thyroid extract. [M.R.D.]

3.—Neumann calls attention to the increase in bodily length, occurring after the disappearance of myxedema. It shows that under thyroid medication, the bones that have previously been impeded in their growth are now stimulated to

renewed vigor. It is always to be assumed that the body has previously been saturated with the unknown substance contained in the thyroid gland, but the effect of this internal secretion is not always proportionate to the amount thrown into the system. The psychical disturbances in cachexia strumipriva in the adult and larger children, can, as is well known, be alleviated. It is emphasized that treatment must be instituted as soon as possible after the occurrence of the disease, if any beneficial result is to be expected. The drug should be cautiously administered as the tolerance in children varies. [M.R.D.]

4.—Warnekres discusses the various bandages that have been devised for the fixation of fractured jaws, with the report of several cases illustrating some of the author's modifications. [M.R.D.]

5.—The author considers the continued administration of **bromide** of potassium as not only unnecessary, but actually harmful in nervous diseases (epilepsy excepted). He is opposed to the administration of **alcohol** in these cases and believes that as a remedy it can be entirely dispensed with. In cases where a stomachic is indicated, the drug can be replaced. Under no circumstances does he consider the routine administration of alcohol justifiable for the purpose of combating fear, anxiety and precordial pain, or for the purpose of producing a state of well being in the patient. Alcohol should be forbidden from the beginning of the treatment. Excitement should be avoided, but this is sometimes impossible when the patient is allowed to remain at home. **Rest** should be insisted upon and regularity of habits enforced. **Hydrotherapy** instituted at home is of the greatest value. There are times, however, when it can not be employed as there are patients with hypochondriacal tendencies who complain bitterly of headache and itching of the skin after the bath. **Electricity** is of great value at home. The author protests against allowing the patient to apply the electricity himself. The faradic and galvanic currents are sometimes entrusted to the patient, who is certainly unable to objectively determine their strengths or indication. The most popular and also the most abused remedy employed at home is massage. Localized massage over nerve exits, painful areas, etc., should only be performed by the physician. The psychical treatment of patients at home is difficult because they cannot be kept under control. Hypnotism, which has been admitted into the therapeutics of nervous diseases, is of value provided it is employed by him who has constant charge of the routine treatment. [M.R.D.]

December 10, 1900. [37. Jahrg., No. 50.]

1. From the University Ophthalmological Clinic at Breslau: Remarks on Scrofulosis and Tuberculosis with a Contribution to Tuberculosis of the Conjunctiva. W. UTHOFF.
2. The Functional Capacity of the Fatty Degenerated Heart Due to Aortic Insufficiency. A. HASENFELD.
3. An Experiment in the Cure of Hernia of the Lungs. O. VULPIUS.
4. Dietetic Treatment of Hyperacidity. E. v. SOHLERN.
5. Diabetes Mellitus. C. v. NOORDEN.

1.—Uthoff believes it justifiable to still further restrict the term "scrofulous." Especially in diseases of the eye the so-called "scrofulous," but not truly tuberculous affections, occur in tuberculous subjects. Tuberculosis itself frequently prepares the soil for the so-called scrofulous diseases. Although the **phlyctenule** most frequently occurs in scrofulous and tuberculous children it should not be considered as directly characteristic of scrofula. The author has observed in his clinic, in a certain relatively small percentage of cases, that phlyctenules occur without the slightest symptoms or history of scrofula, tuberculosis, or previous disease of the eyes. Bacteriological examination of the phlyctenule has not yet demonstrated the etiologic factor. According to the experiments upon animals, made by Valude and others, the healthy conjunctiva does not present a portal for the entrance of the tubercle-bacilli. The author believes that as a whole the conjunctiva does not easily absorb infectious materials as can be seen per example in diphtheritic conjunctivitis, which frequently exists without any systemic disturbances. In certain experiments that have

been made with the toxin of pest, inoculation into the conjunctiva produced positive results by reason of the fact that the poison was conveyed through the **lachrymonasal passages** into the nasopharyngeal space. The author reports a case of tuberculosis of the conjunctiva occurring in a girl of 15 years, whose brother had died of tuberculosis. There had been a previous prelacrymal abscess on the left side that had undergone spontaneous suppuration, and had left a fistula with impediment of breathing on the affected side. The upper and lower palpebral conjunctivae showed a condition which could easily, and was at first, diagnosed as **trachoma**. There was swelling of the preauricular and cervical glands. Examination of the nose and pharynx showed marked changes in the mucous membrane and the formation of granulation tissue. Microscopical examination of excised portions of the conjunctiva from the **lower lid** established with certainty that the process was of a **tuberculous nature**; but those portions taken from the **upper lid** showed **no signs** of tuberculosis, but simply chronic hyperplasia. Regarding the latter it is still to be determined whether this nonspecific portion of the process is caused by the tuberculous area. Either it is due to the toxic effect of the tubercle-bacilli which causes chronic thickening, by reason of a long continued influence, or the continued irritation due to the presence of these toxins may give rise to secondary changes in the conjunctiva without any specific influence being exerted by the toxins themselves; or finally there may be a mixed infection in such a long exposed tuberculous area, whereby organisms other than the tubercle-bacilli may give rise to the secondary involvement. That non-tuberculous changes may occur in tissues surrounding tuberculous areas is illustrated in other tuberculous inflammations of mucous membranes such as pleurisy, meningitis and arthritis. [M.R.D.]

2.—Hasenfeld coincides with Romberg in believing that sufficient proof has not yet been produced to determine the relation that exists between **valvular lesions of the heart and coexisting fatty degeneration of the heart muscle**. The author produced both of these conditions experimentally upon well-developed guineapigs as follows: The carotid artery was exposed, a fine sound with a small terminal bulb was then passed into the artery until the aortic valves were disturbed; the artery was then ligated and the wound closed with collodion. During the whole procedure rigid asepsis was observed. The subsequent detection of the diastolic murmur and the characteristic pulse showed that the artificial production of the lesion was successful. The absence of infection and fever in every case showed that neither the endocardium nor myocardium were infected. After the aortic insufficiency had existed from two to three months (this time was allowed to elapse in order to facilitate the production of fatty degeneration), the animals were poisoned with phosphorus, a time being selected in each instance at which it could be assumed that hypertrophy had already developed in proportion to the valvular defect. Increased functional activity was experimentally produced by ligating the thoracic aorta. After an exhaustive description of the experiments which embrace detailed observations the author comes to the following conclusion: (1) Animals with aortic insufficiency bear phosphorus poisoning much poorer than normal animals; (2) a heart that is hypertrophied by reason of aortic insufficiency has a particular disposition to undergo fatty degeneration; (3) a moderate amount of acute fatty degeneration has no influence upon the power and functional capacity of the hypertrophied heart-muscle, neither under ordinary nor increased functional activity; (4) a marked amount of acute fatty degeneration gives rise to a decrease in strength in the heart with aortic insufficiency, and even fatal circulatory disturbances. [M.R.D.]

4.—Practical experience has shown the author that the carbohydrates, as a rule, not only agree well in patients with hyperacidity, but also hasten recovery. The influence of various foods upon gastric secretion is extensively discussed, as well as the value of various continental mineral waters. [M.R.D.]

5.—In concluding his retrospect of diabetes mellitus v. Noorden states that **decreased absorption** of fats and nitrogenous materials indicates a disturbance of pancreatic secretion. Pancreatic diabetes is still hypothetical. But little progress has been made in the treatment of the disease.

The influence of opium, antipyrin, etc., is not constant but transitory. While considerable has been attained by dietetic treatment, and although we are today better than ever in the position to influence metabolism in diabetes, we are still far from being masters of the situation. [M.R.D.]

December 17, 1900. [37. Jahrg., No. 51.]

1. Amyloid Degeneration, with Special Regard to the Kidney. M. LITTEN.
2. A Few Remarks Concerning the Fermentation and Digestion Tests of Feces and the Value of the Test Diet in the Examination of Intestinal Diseases. A. SCHMIDT.
3. The Relations Observed in the Oxidation of Urinary Constituents. A. JOLLES.
4. Pressure Irrigations in the Treatment of Acute and Chronic Gonorrhea. R. KUTNER.

1.—Litten believes that **tuberculosis** is the cause of 50% of cases of amyloid degeneration. Other conditions giving rise to amyloid degeneration are scrofulosis, suppuration of the skin, bones and mucous membranes, syphilis, ulceration of the intestines, malaria, pyelitis, carcinoma, long-continued leg ulcers, chronic bronchitis, gout, empyema, spondylitis and abscess of the lung. He believes that **carcinoma** is not as frequently the cause as is supposed, for there is only amyloid degeneration with accompanying suppuration. But when this occurs it generally runs a rapid course, there being hardly sufficient time for the establishment of an amyloid degeneration. The author believes that amyloid degeneration may also arise without any assignable cause, in support of which he quotes E. Wagner who had observed 7 such cases. Among a hundred cases of amyloid degeneration observed by the author, there was amyloid degeneration of the spleen in 98% of the cases, of the kidneys in 97% of the cases, of the liver in 63%, and of the intestinal mucous membrane in 65% of the hundred cases. The author describes 3 forms of amyloid degeneration of the kidney: 1. Pure amyloid degeneration of the vessels with and without fatty degeneration of the cortical epithelium. 2. Amyloid degeneration with chronic parenchymatous nephritis (large white amyloid kidney). 3. Amyloid contracted kidney. In the first form the parenchyma of the kidney may be entirely intact, without any sign of fatty degeneration of the epithelium, while the vessels on the other hand may be the seat of amyloid deposit from the merest trace to an amyloid degeneration involving all the glomeruli as well as other capillary areas. It occurs, however, that certain capillary areas are exclusively affected by the amyloid change, such as the glomeruli, interstitial capillaries of the cortex and the vasa recta of the medullary portion; more frequently, however, the disease is more diffuse, embracing several capillary areas including the vasa afferentia and arteries up to the larger branches. The general symptoms of amyloid degeneration of the kidney are then discussed together with the various tests for the detection of the amyloid material. [M.R.D.]

3.—The article deals with a number of elaborate experiments to determine the composition of precipitates formed by the addition of barium chlorid to urine. The composition of these precipitates as is well known differs in neutral and acid solutions. The author arrives at the following conclusions: In each liter of urine the substances precipitated by barium chlorid require in a healthy individual from 198 to 243 mgr. of oxygen for their oxidation. The author shows various methods by which these tests can be controlled. [M.R.D.]

4.—Kutner recommends a method for **pressure irrigation** in the treatment of acute and chronic gonorrhea. A Nélaton catheter is introduced into the urethra for a distance of 4 cm., and a small quantity of irrigation fluid introduced with energetic pressure from a syringe containing from 3 to 4 ounces. The organ is then compressed, permitting the escape of the fluid from the urethra. This is repeated until the contents of the syringe has been exhausted. A model of the syringe accompanies the article. The author believes that this is an excellent method for distending the canal and permitting thorough access of the irrigation fluid. He believes that the procedure is so uncomplicated that it can be employed with advantage as a matter of routine practice. [M.R.D.]

Wiener klinische Wochenschrift.

November 22, 1900. [13. Jahrg., No. 47.]

1. The Question of the Identity of Pemphigus Neonatorum and Impetigo Contagiosa. RUDOLF MATZENAUER.
2. A Case of Gonorrheal Endocarditis. LUDWIG STEIN.
3. The Action of Iodoform and a Substitute for It. ALEXANDER FRAENKEL.

1.—Matzenauer remarks that clinically the predominant symptom of **impetigo contagiosa** is the formation of a crust or scab which is usually wanting in **pemphigus**; and Fox considers this characteristic a basis of diagnosis. Other authors, however, think that the scab-formation depends much upon the age and condition of the patient. **Impetigo contagiosa** belongs essentially to very young children and the confluent pustules often assume the circular form. While **pemphigus** sometimes occurs in the newborn, yet it is not rare in infants from 2 to 4 years of age, and also occurs in older children, and even adults. Histologically the two are so similar that a description of one will serve for the other also. [W.K.]

2.—Stein reports a severe case of **gonorrhea** in a man, 22 years old, who was treated with copaiba during the first 2 weeks. An eruption appeared, resulting in his entering a hospital where he was treated as a case of typhoid fever, without any local treatment to the gonorrhea for 2 weeks more. Then he was admitted to the surgical ward of the Vienna General Hospital, with a large periurethral abscess, upon which Professor Gussenbauer operated. His heart at that time was normal. Gonococci were found in the pus from the abscess. Two days later pain appeared in the fingers, but no swelling. Small hemorrhages in the skin followed during the next few days, and 7 days after operation he died. The autopsy showed **vegetative endocarditis of the mitral valves**, with parenchymatous degeneration of the heart, liver, and kidney. There were a purulent bronchitis, hemorrhage into the pericardium and pleura, and a purulent prostatitis. Weichselbaum found streptococci in his case, and supposed that the gonococcus simply made the soil favorable for the action of the other bacteria. Stein believes, too, that there is generally mixed infection when endocarditis follows gonorrhea. [M.O.]

3.—Fraenkel divides his study of the action of **iodoform upon wounds** into histological researches and clinical observations. From experiments, he shows that iodoform causes the formation of giant-cells, often acting as a foreign body, yet accompanied by more exudate, more signs of inflammation, and more connective-tissue production than when the other sterile powders were used. It is therefore often harmful in abdominal wounds, as it delays healing on account of these changes. In tuberculosis, on the contrary, it is of **great benefit** just because of these actions. Yet Fraenkel thinks that we should seek something else, which will favor the growth of connective tissue, without any possible harmful or poisonous effect. Taking the known effect of coal upon tuberculosis, as seen in miners, as an example, Fraenkel used sterilized **animal charcoal** in 21 cases of local tuberculosis. In no case was that inflammatory reaction, which is the rule when iodoform is used, seen. The results were excellent, though the scars frequently were greatly discolored by the charcoal. [M.O.]

November 29, 1900. [13. Jahrg., No. 48.]

1. Radical Operation in Cancer of the Uterus. E. WERTHEIM.
2. The "Thread" Serum Reaction. PHILIP EISENBERG.
3. A Case of Tetanus Cured by Tizzoni's Tetanus Antitoxin. EDMUND HOMA.

1.—Because of the dissatisfaction with the results of **vaginal operation for uterine cancer** and the large percentage of recurrence of the disease, Wertheim determined in all such cases to remove, by abdominal section, the organ itself and also the parametrium; and having thus treated 33 cases reports the result. Of these, 11 were carcinoma of the body, the others were cancer of the cervix and portio vaginalis, of which 5 were far advanced and 5 in the very early stage of the disease. The mortality was very great, the deaths being 11, 8 of which, however, were due to the weak-

ened condition of the patient and the bad heart-action in consequence of the long narcosis. After this experience he would not again operate in similar cases. Only 3 deaths, then, were the direct result of the operation, 2 from peritonitis and 1 from invagination of the small intestines. Of the other 22 cases, 3 were only palliative operations, 2 died from some other disease, and 17 made a good recovery; and it is noteworthy that in these there has as yet been no recurrence of the cancer. When the cancerous tumor is large, extending itself in all directions and is immovable, or when there is a widely extended cavity, it is doubtful whether operation should not be refused; but when the tumor is still sensitive and small in size, the decision is not difficult and there should be radical operation. If the parametrium is soft and elastic the cancer is still localized. In 11 cases of the series reported microscopic examination determined carcinoma of the uterus, in only 3 of which did the clinical examination lead to the true diagnosis. Taking all things into consideration, Wertheim believes from his experience that one should not shrink from further advances in the beaten way, since it is an attempt to bring recovery to women otherwise doomed to an early death. [W K.]

2.—Eisenberg reports a case of **colicystopyelitis** in a girl of 18, from whose urine, collected by catheterization, a pure culture of *Bacterium coli* was obtained. The patient's blood-serum gave with this culture an "agglutination," and later a typical "thread" reaction, even when diluted 1 to 600. Not one of the many colon bacilli cultures from her stools agglutinated, or gave the "thread" reaction. This "thread" reaction was present in cases of typhoid fever which gave the Widal reaction, not in those which did not. The serum of immunized horses also gave the typical "thread" reaction. It has also been obtained with human or dog's blood from healthy individuals, with typhoid or colon bacilli. He believes, with Kraus, that the reaction simply accompanies the "agglutination," and, contrary to Pfaundler's opinion, is not to be regarded as specific. He gives the literature of the subject. [M O.]

3.—Homa reports a case of **tetanus** in a boy of 9, whose toes were frozen. Trismus followed, and gangrene set in in both feet, for which a Chopart and a Pirogoff amputation followed. The first tetanic spasm came on 6 hours after operation. Tetanus bacilli were found in the discharge, and the Tizzoni antitoxin given. As many as 47 attacks occurred in 24 hours, yet the child recovered 4 months later. [M O.]

December 6, 1900. [13. Jahrg., No. 49.]

1. The Treatment of Peptic Ulcer of the Stomach. ANTON GLUZINSKI.
2. Blood Pressure and its Relation to the Lymph Circulation. FRIEDRICH FRIEDMANN.
3. Phlegmonous Appendicitis Resulting from Tonsillitis. RICHARD KRETZ.

1.—After reviewing the literature of the subject, Gluzinski states that about 30% of cases of **ulcer of the stomach** recover, the greatest number dying of perforative peritonitis. The majority of the ulcers occur in men; and their most frequent seat is about the pylorus. There is usually stenosis of the pylorus, such cases eventually coming, as a rule, to operation. Prophylactic treatment should be instituted in all cases in which injurious substances are swallowed, in anemia and the infectious diseases, and when local congestion exists. This is accomplished by diet and rest in bed, as Leube advises. Medical treatment should extend over a period of one to two years. When there is hypersecretion of the stomach, peptic ulcer may be suspected. When atony exists, with stenosis of the pylorus (probably but a functional spasm due to the presence of an ulcer near by), Gluzinski treats by diet (to hinder stagnation and fermentation, and to diminish the acidity) and lavage through a double bougie. This he continues for 30 to 40 days, causing the cessation of symptoms if the stenosis be functional; but when it is mechanical he advises operation. All cases destined for operation should be got into good condition before the operation. If there should be any possibility of the ulcer becoming carcinomatous, operation should not be postponed. The presence of cancer is proved by the examination of the stomach-contents. After operation, lavage must frequently be kept up for some time. Should perforation occur, opera-

tion must be immediate. Perforation occurs mostly through the posterior wall of the stomach. Hemorrhage, while frequent, is hardly ever of itself fatal. When the hemorrhage occurs too often, operation must be performed. [M O.]

2.—Friedmann reports a case of **lymphatic leukemia** in which emphysema with chronic bronchitis existed, from cardiac insufficiency. Digitalis caused these signs of cardiac insufficiency to disappear in 4 days, with a marked reduction of the lymph-glands. The swelling that remained was much softer. The relation of the erythrocytes to the leukocytes was 39:1, while that of mononuclear leukocytes to polynuclear leukocytes was 93:7. A week later reds were to whites as 83:1. Digitalis was again given for another week, when reds were to whites as 61:1. Under later trials of the digitalis, the swellings decreased in size and consistency, yet the lymphocytosis increased. He explains this action as the effect of the increased blood-pressure from the digitalis, causing an increased outflow of lymphocytes from the lymph-glands into the blood. [M O.]

3.—Kretz reports the autopsies of 2 patients in whom **phlegmonous appendicitis** occurred with a diffuse purulent peritonitis. There was also a purulent tonsillitis, which had passed unnoticed during life, and in the pus from both places, streptococci were found. In the second case influenza bacilli were also seen. He supposes that the appendicitis was due to the virulent bacilli being swallowed. Kundrat has reported a case of phlegmonous gastritis following tonsillitis. Perhaps other obscure intestinal affections may have been caused thus. [M O.]

December 13, 1900. [13. Jahrg., No. 50.]

1. The Action of the Röntgen Light upon the Skin. KIENBÖCK.
2. Some Experiences with Local Anesthesia by Schleich's Method. V. FRIEDLÄNDER.
3. An Aseptic Bougie for Inducing Abortion. LUDWIG KNAPP.

1.—After describing a number of researches Kienböck concludes that the skin exposed to the Röntgen light undergoes peculiar changes. An acute or chronic dermatitis follows, accompanied by a shedding of the horny epithelium, and sometimes of the nails and hair also. Alopecia may result. Hyperemia and inflammatory swelling may come on, or blisters with serous or purulent secretion, or the skin may be dry and burned, the bloodvessels may be much affected, and there may be much pain. As a rule this does not extend deeply, the underlying muscles not being at all harmed. These effects only become apparent after an incubation, or latency, of 2 to 3 weeks. Only in few cases is the alopecia permanent, the hair usually growing again. **The intensity of the skin affection depends upon the length of the exposure and the number of exposures** to the Röntgen-rays. The smaller the amount of light, the longer is the latency before the symptoms appear. The different parts of the body react differently, and individual idiosyncrasy seems unknown. The younger the patient, the greater is the reaction. [M O.]

2.—The late Professor Albert, during the past year, operated upon 30% of his cases with **local anesthesia** by Schleich's method. In the out-patient department, all kinds of operations were done with it. Friedländer considers the technic, as described by Schleich, as important. He experimented to determine the sensitiveness of the different parts of the body. Yet when made edematous by the injections, there is but slight sensitiveness left. When the tissue is inflamed, its sensitiveness increases. Friedländer advises the use of Schleich's method in all skin operations; in operations upon the extremities; in operations in the abdomen; and in all operations where ether or chloroform are contra-indicated. [M O.]

3.—Knapp describes a **uterine bougie**, easily made aseptic, which he uses to produce abortion. It is similar to an ordinary male catheter. [M O.]

December 20, 1900. [13. Jahrg., No. 51.]

1. The Difference between Natural and Artificial Nourishment of Infants. THEODORE ESCHERICH.
2. Observations upon Workers with Electricity. S. JELLINEK.
3. Hyperchlorhydria in Infants. WILHELM KNOEFELMACHER.

1.—After comparing the results obtained by artificial feeding with breast fed babies, Escherich says that **rachitis occurs no oftener in the one than in the other**, though the more severe cases are seen among the bottle-fed. He has not seen a case of infantile scurvy among thousands of infants fed artificially or upon sterilized milk. He then discusses the assimilation of the food taken by an infant, laying stress upon the relative absence of the diastatic ferment in cow's milk, and upon the failure of the normal changes in digestion and absorption of cow's milk, as compared with mother's milk. Yet some infants evidently thrive upon pure cow's milk. He then elaborates upon the hypothesis that mother's milk contains "some stimulating and tonic material." [M.O.]

2.—Jellinek studied the blood-pressure in 80 men, from 20 to 30 years of age, at work with electricity. He used **Gärtner's tonometer**. The mean blood-pressure varied from 100 to 120 mm. of mercury. He details a number of experiments undertaken, which may lead to later developments. [M.O.]

3.—Knoepfelmacher reports the case of an infant of 10 months, born at 8½ months, and breast fed to 7 months. Then, as symptoms of motor insufficiency of the stomach had appeared, she was slowly changed to cow's milk. Examination of the stomach-contents showed **marked hyperchlorhydria** (0.95%). The history, as reported, suggests **congenital stenosis of the pylorus**, from the vomiting, constipation, loss of weight, and dilation of the stomach. This confirms the theory of Thomson and Pfandler, that the spasm of the pylorus follows hyperchlorhydria. The child thrived on pure cow's milk. [M.O.]

December 27, 1900. [13. Jahrg., No. 52.]

1. Thomsen's Disease. MAHLER and BECK.
2. Splenectomy for a Movable Hypertrophied Spleen. KARL SCHWABZ.
3. A Modification of the Breisky Speculum. LUDWIG KNAPP.

1.—The patient, aged 24, was the son of wedded first cousins, in whose family no nervous diseases had ever existed. As an infant he had rachitis, and later measles and pleurisy. He did not walk until 4 years old, and then had trouble in moving his legs. When at school, he first observed that his movements, especially during exercises, were always somewhat behind those of the others. This improved, then grew worse at puberty, then better again. He passed the physical examination for the army at 20, but was found unfit for service on being reexamined. Since then, he has grown worse. Rising from bed and raising his glass to drink, in the morning, are both very hard. If he hurries, or is bumped, his muscles become stiff and he falls. He feels a tickling on his face and neck, which often causes twitching. His reflexes are normal, except the plantar reflex, which is absent, as is ankle clonus. Voluntary movements, in the extremities especially, show high-grade muscle-weakness. Continued slow effort was needed to move at first, but if repeated, he succeeded in going quicker. If he made an energetic or sudden movement, tonic contraction of the muscles followed. Though the muscles all looked well developed, the muscle-power was very low. The movements of chewing were very difficult. In fact, the patient presented the typical picture of **myotonia congenita**. The condition in the extremities, almost one of paralysis, Mahler and Beck call paramyotonia, after reviewing the literature of the subject. They consider Thomsen's disease purely a spinal affection. In their case there were no disturbances in assimilation. [M.O.]

2.—Schwarz reports a case of **movable spleen** which was first noted 12 years before, in a woman now aged 36. This movable tumor grew in size and caused so much pain that the patient remained in bed, off and on, for weeks. She never had malaria; nor were there any signs of syphilis. Laparotomy was performed and a spleen which weighed 1200 grains removed. It was then discovered that she was 5 months pregnant. Recovery followed. Schwarz concludes that splenectomy is always preferable to splenopexy, except when strong adhesions exist. Especially when the spleen is hypertrophied should splenectomy be done. [M.O.]

3.—Knapp describes a simple contrivance by means of

which the Breisky speculum will support itself, when introduced into the vagina. [M.O.]

Centralblatt für innere Medicin.

January 5, 1901. [25. Jahrg., No. 1]

1. Histological Changes in the Central Nervous System and Stomach in a Case of Gastric Tetany. FERRANNINI.
2. On the Auscultation of the Normal and Pathologic Muscle Sounds and the Characteristics of the Same in Thomsen's Disease. M. HERZ.

1.—Treated editorially.

2.—Herz draws attention to the fact that there has never been sufficient study of the sound given by a muscle during its contraction. He divides this sound into two portions: one a musical part, which he calls the muscle-tone, and the other a mere noise. It has been shown that in tetanic contraction of muscles produced by electricity the pitch of the tone is dependent upon the rapidity of the interruption of the current. The tone can be produced by chemical irritants, and by strychnia poisoning. One can readily hear the muscle-sound when the muscle is in tonic contraction. If the patient stands upon the tips of his toes, leaning with his hands on a piece of furniture or against the wall, the sound can readily be auscultated in the calf-muscles; or by pulling upon something with the hands it can be auscultated over the biceps; by raising the arm the deltoid will give a sound; and so by various other methods other muscles may be auscultated. It is not necessary to expose the skin. Pathologic changes are readily recognized. The intensity of the sound, its character and pitch are variable, and variations may be readily determined. If the sound is loud the tone becomes deeper and the sound is sonorous. Curiously this character of the sound is found most frequently in cases of disturbed innervation. Strong muscles give a sound which he characterizes as soft, high pitched, and hollow. He believes that important conclusions may be reached by farther study of the muscle sound. One of the most important things to be studied is the course of accidental murmurs over the heart. It is important, he believes, to investigate the relation between the changes in the heart tone and coincident changes in the muscle sounds elsewhere. It is also important to make special studies of the sound in anemic conditions, particularly in chlorosis, in cachexia, in fevers, in the gouty diathesis, in diabetes, etc., and of course in various nervous affections, particularly in neurasthenia and neuroses. He has found a marked difference in the sounds on the affected and unaffected sides in cases of hemiplegia. It may also prove important to study the sound before and after various therapeutic procedures. In a case of Thomsen's disease he made a careful study of the muscle sound, and found that in the beginning of the peculiar contractions he heard no sound, and his observation was confirmed by Lampa. Later on, by continued auscultation, the muscle sound gradually appeared and became of normal strength, and at this time the muscular spasm had disappeared. If the disease were due to a central origin and the spasm were similar to that of tetanus the muscle sound should be loud; if the change, however, were in the muscle fibrils, and consisted of a sharp contraction of the fibers with a fixation of the fibers in this position, and no further vibrations, the muscle sound would be absent. The latter was the case. [D.L.E.]

Zeitschrift für Heilkunde.

[Volume xxi (New Series, Volume 1).]

[Jahrg. 1900, No. xi.]

1. The Treatment of Tuberculosis with Intravenous Injections of Cinnamic Acid. (Conclusion). KARL HÖDL-MOSER.
2. Gynaecological Communications. MAHER.
3. The Diagnosis of Retroperitoneal Hernia, with Report of a Case. WILHELM SCHÖLL.
4. The Bremer and Williamson Blood Reactions in Diabetes Mellitus. EMIL ADLER.

1.—These injections were given 18 patients, daily, from 1 to 6 months. Sixteen of them had phthisis, 1 had tubercular peritonitis, and 1, tuberculosis of the lungs and joints. Eleven were seen in the Vienna General Hospital, while 7 came to the dispensary. After an extensive review of the statistics already published, Hödlmoser gives his results, which, in marked contrast to those collected by F.änkel, 90% improved, and those reported by von Weismayr, 74% improved, give **only 22% improved**. Whether such results are really due to the cinnamic acid, further investigations alone can show. With Ewald, Hödlmoser pleads that further experiments be undertaken. The case-histories follow in detail. [M.O.]

2.—These consist of 19 case histories from the Rndolph-Spital in Vienna. Among the more interesting cases are the following: (a) a coachman, 33 years old, entangled in a broken wire which crossed a trolley-wire, was thrown to the ground, badly shocked. The **quadriceps muscle** of both thighs was **thrown into tetanic spasm**, which lasted 24 hours. The stiffness in both legs remained 2 weeks. Had he not worn nonconducting leather trousers, he would most probably have been paralyzed. (b) A case of **acute angio-neurotic edema** in a man of 28 years, occurring several times during 6 months, in different parts of his body, for which no cause could be found. (c) A woman of 40, on whose upper lip a **carbuncle** suddenly formed. **Phlebitis** followed in the facial vein, followed by **thrombophlebitis of the cavernous sinus**. **Metastatic abscesses** occurred in **both lungs with bilateral fibrinopurulent pleurisy**. Death followed 5 days after the carbuncle appeared. (d) A woman of 54, swallowed a spoonful of **ammonia**, 7 hours later she reached the hospital, and was given diluted vinegar in large quantities. She vomited a brown alkaline fluid. While hoarse, she complained only of slight epigastric pain. Her mouth was sore, yet she drank milk and soup easily. She died suddenly, 24 hours after taking the poison. The autopsy showed **intense corrosion of the mouth, trachea, esophagus, and stomach**, in spite of the very few subjective symptoms. Striking, too, was the lack of dyspnea and cough. Mader supposes that the ammonia affected the deep nerve-roots, causing anesthesia and analgesia. (e) A woman of 41, with **chronic phthisis and pyothorax**, had suffered for over 4 years with increasing nervous symptoms, weakness, spasticity of the extremities, paresthesia, twitchings, and finally paralysis and wasting. From the many small swellings along the peripheral nerves, the diagnosis of **polyneuroma** was made. Death followed from phthisis. The autopsy showed **various sized tumors upon almost all the nerves of the body**. Two plates show these well. Their immense number is striking. (f) A locksmith, aged 29, who for 2 years previous had had chills and fever when exposed to cold weather, was admitted after such an attack, with **hemoglobinuria**. His liver was swollen and painful. He had suffered from malaria during childhood. Cold applied locally had no effect. Hemoglobin was 75%, erythrocytes 4,400,000, leukocytes 2,000. With iron, arsenic, and good food, he quickly recovered. A number of cases of hysteria, some cases of brain tumor, and of chronic lead poisoning are also described in full. [M.O.]

3.—The patient, a 22 year-old girl, weak and poorly developed, had always had a **distended abdomen**, with occasional disturbance of digestion. The abdominal distention increased during the last two years, with several attacks of pain, followed by the passage of flatus and sudden improvement. She kept at work until 3 weeks before her death. After a week of constipation, with great pain and distention, she entered the hospital. She was pale and thin. Her heart was pushed upward and to the right. There was very little expansion on the left side of the thorax. On the right side, tympany began at the sixth rib; on the left, at the third rib. The **abdomen was enormously distended**, showing dilated veins. **No tumor was at any time palpable**. The **ascending and descending colon** could be made out, **widely dilated**. There were no ascites, no vomiting, and no hiccup. She had diarrhea generally. Symptoms of peritonitis only appeared during the last 12 hours. As the case was not diagnosed during life, operation was not considered. The autopsy revealed a **retroperitoneal hernia**. The greater part of the jejunum, having passed through and stretched the opening in the peritoneum for the colica

sinistra artery, was found behind the descending colon, extending up to the pancreas, and down to the sigmoid flexure. The diaphragm reached up to the third rib; the **heart lay almost perpendicular** under the right edge of the sternum. The sigmoid flexure was normal. The rest of the colon was dilated, with greatly thickened walls. In the **descending colon** were a number of **oval perforations**. The pressure of the filled jejunum was the evident cause of the stenosis and subsequent perforation. Though over 70 such cases have been reported, the majority were not diagnosed until the autopsy revealed a retroperitoneal hernia. Jonnesco has divided them into 4 groups: (a) The majority, found post-mortem, having caused no symptoms; (b) those having caused but slight digestive disturbance; (c) some few, in which progressive stenosis of the intestine followed; and (d) those with sudden strangulation and death. Of group c, **only 3 other cases** have been reported up to this time. Scholz quotes them in detail. He then calls attention to the **very large abdomen and very small thorax**, and to the **great distention of the large intestine**, both points in the diagnosis of retroperitoneal hernia. Digestive disturbance from early childhood, and a tumor, when present, also aid in forming the diagnosis. [M.O.]

4.—Adler tested the reactions which, it was claimed by Bremer and Williamson, occur in staining diabetic blood. Bremer claims that, with a methylene-green eosin mixture, diabetic blood is stained green, while other blood stains red. Williamson claims that diabetic blood takes a **warm alkaline methylene-blue stain more deeply than other blood**. Out of 25 cases tested for the Bremer reaction, Adler found it in the blood of 5 severe cases of diabetes mellitus, in 2 cases of leukemia, and in 1 perfectly well man. Other investigators have published like results, showing the **Bremer reaction to be of no diagnostic value**. The Williamson reaction was tested in 130 cases. It was **positive in all cases of diabetes mellitus tested (9)**, and in **no other disease, no matter how great the glycosuria**. The cause of this reaction Adler believes to be a diminution in the alkalinity of the blood. He concludes that the **Williamson reaction is peculiar to diabetic blood, and of value in diagnosis**. The details of his method of staining are given. [M.O.]

1.—To be treated editorially.

2.—Aron describes at length an apparatus which he has used for the study of the question at issue. His tables show that there was a distinct reduction of the amount of oxygen used in rarefied atmosphere and also a marked reduction of the amplitude of respiration. If oxygen were given the amplitude of respiration approached close to that observed before the air was rarefied, but this could not be fully attained. He therefore decides that the cause of the alteration in breathing in rarefied atmosphere is both a chemical and a physical one. He believes that he is justified from his results in recommending that trains passing over high altitudes, such as the proposed Jungfrau road, should have oxygen cyl-

inders in the carriages and at the stations, as he believes that in this way it would be possible to avoid serious attacks of mountain sickness, and in some cases probably to avoid death. [D.L.E.]

3.—The teaching which Thomas follows is that first promulgated by Bard, that the occurrence of **cyanosis** depends upon an increase in the pressure of the left auricle as compared with the pressure of the right. Bard previously taught that this was usually due to some persistence of the foramen ovale, the opening being closed by a membranous valve and the valve driven open if the pressure in the left auricle became very high. Bard afterward reported cases himself in which cyanosis of a severe grade (blue sickness) was seen without any persistence of the foramen ovale, but in which a considerable portion of the lung parenchyma was destroyed by tubercular infiltration or other causes. If the bloodvessels are not destroyed with the parenchyma of the lung, the result will be that a very considerable proportion of the venous blood will pass through areas in which it is impossible that the blood should be aerated. In such cases cyanosis will result. If the bloodvessels were destroyed or obliterated with the lung parenchyma the blood would then pass through the remaining more healthy parts of the lung and cyanosis would probably be slight or absent; hence the preservation of the bloodvessels in areas where the lung is destroyed tends to cause cyanosis. Thomas reports a case of this kind, and refers to others. [D.L.E.]

4.—Bönninger has investigated a number of methods for the determination of the **fat in the blood**, and finally selected that recommended by Hoppe-Seyler as the most satisfactory. The method of carrying this out is to take from 5 to 30 grams of blood, receiving it in 20 times its volume of 96% alcohol, mix thoroughly, allow it to stand for from one to two days, and filter. The deposit collected upon the filter is to be treated again in the same manner; the part then remaining is treated with ether, and the remaining portion digested and then thoroughly shaken with ether. The various alcoholic and ethereal extracts are collected, evaporated slowly to dryness, extracted with absolute ether, thoroughly dried and weighed. A considerable portion of the fat is likely to be held back in the filter paper, hence the filter papers are extracted with ether in the Soxhlet apparatus. This method gave extremely satisfactory results. The amount found in normal blood was fairly constant and between 0.75 and 0.85%. The highest amount of fat was found in a case of carcinoma of the esophagus, where it reached 1.4%. This is probably a further proof of a statement that has been previously made that the fat of the blood increases in hunger; this patient had been able to take practically no food for some time. A similar cause may have been active in a case of pneumonia in which the fat reached nearly 1%. It was also found high in diabetes, in a case of nephritis, and in a case of hysteria. The serum was found to contain neutral fat, lecithin and cholesterol. The cholesterol in human serum is united with fatty acids, particularly oleic acid. The blood-corpuscles contain probably only cholesterol and lecithin, and no neutral fat. [D.L.E.]

5.—Adamkiewicz divides **tabes dorsalis** into two forms—one, a primary disease of the nervous elements, he calls nerve-tabes; the other, in which the bloodvessels are first affected, he calls vessel-tabes. The latter is the interstitial form, and involves the neuroglia. Syphilis he considers practically always the cause of the interstitial form, while he does not think it is nearly so active in producing the other form; and perhaps never produces it. The main clinical differences in the two are, that in the parenchymatous form, ataxia occurs, with persistence of the muscular power; while in the interstitial form there is less marked ataxia, but more marked muscular weakness. In the parenchymatous form the skin-sensation is reduced, while in the interstitial form this is not the case; the interstitial cases, as a rule, show no constant reduction of sensation, but do show various paresthesias. Paresthesias are much less prominent in the so-called nerve-tabes. Adamkiewicz goes into an elaborate explanation of the reasons of this difference in sensation. He thinks the chief cause of the variations in the paresthesias is variation in the space occupied by the neuroglia tissue, and this is produced largely by meteorologic conditions. He calls the disturbances of sensation produced by irritation of the ganglia of the posterior roots "subjective," and denominates as objective disturbances those produced by variations in the

acuity of perception of sensations caused by peripheral irritation. These two forms he considers act antagonistically; he describes them as producing waves of sensation, and when one wave is high the other is low. He believes that if, at a certain time, the wave of the subjective sensation be high any normal irritation of the periphery which would ordinarily produce an objective sensation will have no result unless it is sufficiently strong to overcome the subjective wave. This is what he terms the interference of two sensations. In this way he explains the tendency that patients with disturbance of their subjective sensation have of instinctively grasping objects very tightly. The result of this is that their objective sensation is made so much stronger than usual that the patients are able to appreciate the objective sensation, when if the object were grasped lightly the sensation from the object would be less than the subjective sensation, and only an ill-formed objective sensation would result. [D.L.E.]

6.—Runeberg directs attention to a method of examination which is practically nothing more nor less than **auscultatory percussion**. His chief point is that one should place the stethoscope over the organ to be examined and then percuss gently, or stroke the finger tip gently toward the periphery of the organ. So long as one remains over the organ auscultated, the sound, which he calls the trans-sonance-sound, will be clear, but it vanishes or changes its character immediately upon passing the limits of the organ. [D.L.E.]

7.—Neisser describes the case of a man who had had a cough as long as he could remember, but had no definite history relating to his condition. The chief points in the investigation of the man were that he had signs of marked enlargement of the right lung with atrophy of the left lung but without any deformity of the left chest. Neisser thinks that when deformity of the chest is absent and yet there are signs of atrophy of the lung, the condition is probably one that arose either extremely early in life or was congenital. He considers that it is only in very early life when the lungs are capable of very considerable growth, that one lung could so greatly hypertrophy as to fill the space left vacant by the other, without causing chest deformity. The most common and important cause of deformity of the chest is pleural adhesion, but the chest may become deformed without adhesion, as evidenced by several cases collected from literature in which deformity of the chest occurred and subsequently disappeared. He thinks that if pleural adhesions had caused the deformity, the latter would scarcely have disappeared. The conditions which he considers necessary in order that atrophy of the lung shall produce no deformity of the chest are, that it should occur in early life, when the remaining lung is capable of rapid growth, and that it should be of slow progress, so that time is given for hypertrophy of the other lung. In such cases the thorax also really changes to a certain extent, as compared with the normal, so that while there may be no deformity of the two sides, as compared with each other, there will be some deformity as compared with the normal chest. A further evidence that in the case first reported the condition was congenital is, he believes, shown by the fact that a son of the man afterward came under observation and showed the same condition. He believes that the most satisfactory explanation of the occurrence of this condition is congenital bronchiectasis. [D.L.E.]

8.—Edel first refers to the work of Simon, which seems to show that sweat-baths reduce the secretion of gastric juice, particularly the HCl. These results are contrary to those of several authors, particularly Reigel's results with the use of pilocarpin. Some authors have, however, to a certain extent confirmed Simon's results. Edel has further investigated the question, giving warm baths and then covering the patients with thick woolen blankets, and giving them subsequent test-meals. The results of his investigation stated briefly are, that the baths had little effect upon the secretion of gastric juice; the secretion usually remained normal but sometimes increased. Subsequently the acidity was most frequently found elevated. Edel believes that his results are more trustworthy than Simon's, because he used normal persons. As to Simon's belief that the baths cause a persistent decrease in the chlorides of the body fluids, he considers this mere supposition and very improbable, because Simon in no way controlled the intake of chlorides; if there is a loss of chlorides through baths, or by any other means, it is cus-

tomy for subjects to make this up by subsequently taking in larger amounts of chlorides. [D.L.E.]

9.—One recent view concerning chronic lymphatic leukemia is that it is a disease primarily of the lymph glands, which has a characteristic blood picture; the affection of the liver, spleen, and bone marrow is secondary, and produced by metastasis. Another view is that it is a primary disease of the lymph glands, but produces the characteristic blood picture only when the bone marrow becomes involved in the lymphadenoid change. A third view is that it is a primary disease of the bone marrow, which consists of a lymphadenoid degeneration; it may remain confined to the bone marrow, or may secondarily through metastases involve the lymph glands, spleen, etc. The fourth view is that it is a disease of the whole lymphatic tissue, which tissue is preexistent in all organs. Rosenfeld reports 3 cases, and discusses them in connection with the theories of the disease. The 3 cases showed distinct differences in the clinical course, in the condition of the blood, and in their post-mortem findings. In the first case there was from the beginning of observation a very marked reduction of the red cells, while this was but slight in the second case. The number of lymphocytes varied in the 3 cases. The number of lymphocytes in the peripheral circulation is not indicative of the absolute number produced, but it was striking that in the 3 cases the lymphocyte count was 4 times as great as in the second case, and yet in the second case the sole increase was in the small lymphocytes. It is an interesting fact that in this case after treatment with arsenic and an evident decrease in the size of the lymph glands, there was a marked increase in the number of circulating lymphocytes. Probably the reduction of the glands was associated with a flooding of the blood with lymphocytes. One remarkable fact was that in the first case an examination of the blood while the glands were enlarged, but before the actual symptoms of leukemia had come on, showed no marked blood-changes, and the flooding of the circulation with lymphocytes apparently took place 6 months afterward. This was very probably true, also, in the third case, since the lymph glands had become enlarged 3 or 4 years before the severe general symptoms appeared. In the second case, in which the increase in cells was, as noted, practically entirely of the small lymphocytes, the postmortem showed enormous involvement of the lymph glands with very marked involvement of the bone-marrow. The difficulty in this case was as to whether the case was a true lymphatic leukemia, or lymphemia with general sarcomatosis. The diagnosis of the pathologist was the latter condition. In the first case no postmortem was obtained. In the third case there was diffuse lymphadenoid degeneration of the bone-marrow. The third case, therefore, stands between those instances in which there is only involvement of the lymph glands, and other cases in which there is only involvement of the bone marrow. Rosenfeld accepts chronic lymphemia as being one of general lymphosarcomatosis, and thinks that the varying conditions found clinically are due to the varied tissue involvement in the sarcomatous change. He notes the fact that so far as this condition has been studied, when the lymph-glands are involved to the almost complete exclusion of the bone marrow the increase is chiefly or entirely of the small lymphocytes, while when the bone-marrow was chiefly involved, the large mononuclear lymphocytes were in excess. It is also notable that in several cases, at any rate, when the bone-marrow was uninvolved there was practically no change in the erythrocytes. His conclusions are that one cannot deny the existence of a primary disease of the lymph glands which may produce either an aleukemic preliminary stage, or which produces chiefly an increase in the small lymphocytes if the disease has become very widespread. If the bone marrow becomes involved sufficiently, the blood picture changes, and the large lymphocytes become increased in number, and in such cases there is likely to be an onset of severe clinical symptoms and a rapidly progressing course. As to Pappenheim's theory that lymphatic leukemia is primarily myelogenous in all cases, Rosenfeld's second and third cases speak strongly against this. The name, however, given the condition—lymphatic leukemia—should not indicate that the disease is solely one of the lymph glands. It should indicate rather that it is a disease of the lymphatic tissue in general. [D.L.E.]

1.—The practical conclusion which Heichelheim reaches is that in all cases where it is not possible to siphon the stomach in order to determine its motor power one may with advantage use iodipin. The results are not exact, but they give a general idea of the motor power of the stomach, and in connection with other factors in the case one may by this means reach fairly certain conclusions. The method is very easily used. The one condition as yet observed that seems to interfere is icterus, in which the test seems to give the same result as in weakness of the gastric motor power. It was found that in stenosis of the pylorus and gastric ecstasy with motor insufficiency the reaction was practically always delayed beyond 1 hour, though this was not an absolutely constant result. This did not seem to be the case in other gastric affections. The test consists of the administration of about a gram and a half of iodipin in gelatin capsules and testing the saliva every quarter of an hour afterward for the presence of iodine. The test which Heichelheim used was to the reaction with starch paper which had been recently made and kept in the dark after saturating it with 5% persulfate of ammonia. The saliva should be placed in test tubes and a paper put in the tube. It is absolutely important to keep the papers in the dark. [D.L.E.]

2.—Biernacki makes some very interesting observations concerning the method of determining the glycolytic action of the blood. One of the most important points that he discovered is that if different quantities of the blood are mixed with varying quantities of sugar the result is by no means always proportional to the quantities used, and that therefore in order to compare observations one should always use the same quantity of blood with the same quantity of sugar solution, and the latter should always be of the same strength. Also, if the quantity of sugar solution were kept the same, increasing the amount of blood used, it did not seem to have a proportionate influence upon the glycolysis after a certain optimum in the quantity of blood used was once reached. On the contrary, increase in the amount of blood seemed to decrease the glycolysis. The use of alkaline solutions caused much more active glycolysis than did physiological salt-solution. Blood which had not been defibrinated was more active than that which had been defibrinated, and there was a certain direct relation between the glycolytic power of the blood and the amount of water contained therein. He states that in all the cases of diabetes he observed distinctly low values for glycolysis when alkaline serums were used, but concentration of the sugar solution abnormally increased the glycolysis. The absolute values in diabetes, then, were low, but the values obtained by increasing the percentage of sugar were relatively higher than those obtained in health. He does not believe, therefore, that his results indicate that there is any definite loss of the glycolytic power in diabetes; they indicate only that there is disturbance of the glycolytic power, and it is quite possible that these disturb-

ances are not due to changes in the enzyme alone, but to other factors. His observations concerning functional neuroses (chiefly hysteria and neurasthenia) are interesting. The venous blood in both diabetes and functional neuroses is pale. He also found in a number of cases very low values for glycolysis in functional neuroses, though the values varied greatly; a point upon which he lays especial stress is that contrary to the normal conditions defibrinated blood in functional neuroses oxidizes sugar more actively than undefibrinated blood. In other words, the blood in functional neuroses acts as a defibrinated blood. He believes that he is justified in stating that the most characteristic thing about the blood in hysteria and neurasthenia is that in these conditions it resembles defibrinated blood. Whether it is a cause or a result of the disease is questionable. It is, however, in his belief, evident that there is disturbance of the chemistry of the blood in neurasthenia and hysteria, and that there is some relation between neurasthenia and hysteria and diabetes as to their blood conditions. [D.L.E.]

3.—Hoffmann describes a case in a man of 23 which had the following clinical picture. He had always been anemic and weakly and had for a long time had a disturbance of the pulse rhythm which consisted in a pause after two normal beats. Later the intermissions appeared less frequently, afterward attacks of loss of consciousness occurred which lasted for hours, and which were accompanied by extreme infrequency and irregularity of the pulse; strong cardiac contractions occurred after long partial pauses, during which pauses one could hear weak heart tones. By increasing the general nutrition of the patient and by administration of oxygen by inhalation the heart's action became more regular, and the attacks of loss of consciousness disappeared. The chief characteristics of Adams-Stokes' disease are bradycardia, apoplectic attacks, and disturbance of the breathing. This case seems to belong under this head. Hoffmann gives a brief review of the cases of the disease previously reported, and discusses the causation of the peculiar attacks. By observation of the pulse-curve and of the heart with the fluoroscope, Hoffmann determined that the intermissions observed were really an evidence of weak interpolated systoles, as is taught by Engelmann, Wenckebach, and others, and he considers the condition due to lack of contraction in the ventricles while the auricles contract. The cause of the imperfect or slowed action is varied. It may be degeneration of the heart, myocarditis, arteriosclerosis, or central nervous disease, but in the case reported it seemed to be merely imperfect nutrition of the cardiac muscle as a result of anemia. The factor which Hoffmann thinks produces the slowing of the heart is chiefly irritation of the vagus center through anemia of this center, while tachycardia is due to paresis of this center which is often produced through this same cause. His results from the use of oxygen convince him that this treatment may be valuable in these cases. He administered 30 liters daily. [D.L.E.]

4.—The conclusions reached by the authors are, that in concert with other observers they found that the gaseous interchange in obese subjects during a period of abstinence was normal. They, however, make the important statement that they found the increase of gaseous interchange after taking nourishment abnormally low in these persons, and of only short duration. There has been a good deal of discussion whether there is any such thing as adiposity due to an abnormal reduction of the oxidation of fats. If these observations are correct they indicate that in some persons there may be a notable reduction of the fat consumption, which, to a considerable extent at least, explains the abnormal accumulation of fat. The reaction through muscular exercise seemed to vary according to the condition of the organs in general. In one case the reaction was similar to normal. In other instances a relatively slight increase of muscular action caused a very marked increase of the oxygen consumption. They tested the influence of the use of thyroid upon the fat accumulation. In one series of observations they believed that all the loss of weight could be attributed to loss of fluids. In other cases, however, there was certainly a marked increase of tissue consumption. This they could not observe in periods of abstinence, but it was very apparent after taking food, the normal increase in oxygen consumption being much excited under the influence of thyroid. [D.L.E.]

5.—The first question considered is the value of the Widal reaction, and the conclusion reached is that it is of

little value in establishing the diagnosis early. They place it among typhoid symptoms in general, any of which may be absent, and any of which may appear late, and they consider that the diagnosis of typhoid fever from similar conditions must be made through careful clinical observation and the observation of the course of the disease. They report a small series of cases (55); 47 cases gave a positive result, and 8 negative. Of the 8 positive cases 3 gave a reaction only after 5 weeks. One of the negative cases died on the 9th day. In 3 other cases the last test was made on the 9th, 18th, and 25th days respectively, so that these cases can hardly count against the reaction; the 4 others were negative on the 62d, 73d, 86th, and 106th days of the disease. As to the clinical value of the investigation of the spots for typhoid bacilli, they state that they examined 16 cases, and in 14 found bacilli. They insist, however, that the bacilli may disappear from the spots after 3 to 5 days, and that the examination must therefore be undertaken quickly; also it is often necessary to examine several spots before positive results were obtained. Bacilli were always scarce. In examining the spots they always made a number of moderately deep incisions, and then scratched the surface energetically. This method, however, cannot be considered as anything more than an aid in diagnosis, because spots are not present in all cases; because they often appear so late as to be of little value in the diagnosis; because bacilli cannot be obtained from all spots and the bacilli are likely to disappear early; and because it is very easy to confuse a typhoid eruption with other eruptions. Piorkowski's method with the literature concerning it is then discussed. They tested the method with cultures of typhoid bacilli, and various bacilli belonging to the colon group, with satisfactory results, and examined the stools of 19 cases of typhoid fever. In all 123 colonies from the latter were examined, and in three-fourths of the cases they obtained positive results, in one fourth negative. But they insist that while Piorkowski's urine gelatin medium is a valuable addition to bacteriological methods of investigation, a diagnosis can never be satisfactorily made from the appearance of plate-cultures. The bacilli must show the proper chemical and biological characteristics in order that a positive diagnosis may be made. They tried the influence of adding urea and ammonium carbonate, or mixtures of these, to gelatin, instead of using urine. The results were not satisfactory, but they did get satisfactory results from inoculating normal urine with the micrococcus uræ instead of allowing it to become alkaline spontaneously. They note that it is practically impossible to use Piorkowski's method, in summer, however, as the dilute gelatin becomes fluid at a relatively low temperature. [D.L.E.]

6.—Sachs refers to his previous work which had apparently shown that in frogs, after extirpation of the liver, there was a marked reduction of the power of using levulose in the organism, while other forms of sugar seemed to show little change. He has continued his work with the idea of determining whether levulose had any power of increasing the glycogen production elsewhere than in the liver, extirpating the liver and determining the glycogen in the muscles with and without the administration of levulose. He believes that he has shown that there is no distinct increase of the glycogen of the muscles after the use of levulose, and decides that the production of glycogen in the liver is different from the same process in the muscles, since glucose causes an increase in both liver and muscle glycogen. [D.L.E.]

7.—The authors were led to their work chiefly through the suggestion that periodic paralysis is comparable to the action of curare, and may therefore be properly considered to be the result of some similar toxic agent. In the periods of paralysis, during the attacks there is either complete or almost complete loss of the faradic and galvanic reactions of the nerves and muscles. They administered curare to a series of animals, and found that the electric reactions did not disappear, both the faradic and galvanic currents showing an absence of qualitative or quantitative change, even with complete paralysis. Whatever the cause of periodic paralysis may be it cannot be a substance which shows close similarity to curare. [D.L.E.]

8.—To be treated editorially.

10.—Simon believes that his results with pilocarpin have been confirmed by those of Tschurilow and some recent results of Pawlow. He criticises Riegel's results in that in

two cases they showed a distinct decrease of the total acidity; and he thinks that it is quite possible in some of the cases that the increased acidity after pilocarpin may have been due to increased secretion of saliva and the excitation of gastric secretion through the swallowed saliva. He makes some other detailed criticisms which he believes support his view that sweating decreases the acidity of the stomach-contents. [D.L.E.]

3. A Peculiar Gas Forming Bacillus which was Isolated from the Stomach-contents in a Case Exhibiting Troublesome Borborygmus. L. SANSONI and L. FORNACA.

1.—Zaremba gives a very interesting discussion of the literature concerning the protective influence of the various portions of the gastrointestinal tract and the glands connected therewith, but without drawing any very decided conclusions as to the result of this work. He first discusses the work that has been done on the action of the salivary glands. There is some testimony that these organs have a destructive influence upon toxins, but if this exists its influence is probably variable, and nothing very important is known concerning it. As to the gastric juice, it has apparently been shown that not only is inflammation to some extent controlled by the gastric juice, but that toxins are destroyed by it. It is shown to be much more active against certain toxins, such as the tetanotoxin, than against some others, such as the diphtheria toxin. There is considerable probability that the toxins are markedly altered in some way in their passage of the intestinal wall; they thereby become less active. It is also probable that the normal nonpathogenic intestinal bacteria contribute largely to antidoting the toxins present in the intestinal tract and controlling their production. As to the liver, there has been a tremendous amount of investigation. It has been generally accepted by most authors who have not interested themselves especially in this question, that the liver is more active perhaps than any other organ in destroying poisons of bacteria. It is apparently demonstrated that the liver does reduce the activity of a certain kind of poisons, but recent work has shown that there is apparently little difference in the action of many poisons when injected into the portal vein or when injected into the general circulation; it is possible that the liver shows a very different action upon different poisons, reducing or destroying the activity of some, having practically no influence upon others, and even increasing the activity of certain poisons. The general question of the influence of the liver is certainly not settled at any rate. It is fairly well demonstrated that the liver is active in the destruction of poisonous products of metabolism, but its exact influence in connection with poisons absorbed from the gastrointestinal tract is not well known, and is probably variable. The bile seems certainly to have an antidotal influence upon certain forms of poison, particularly snake poison and tetanotoxin. It varies largely according to the percentage of bile present, the age of the animal providing the bile, and other factors. The secretion of the pancreas has been shown to have an antidotal influence upon a number of toxins, but whether this is an influence that may be exerted throughout the general circulation, or is dependent upon contact of the pancreatic juice with the toxin is doubtful; the latter seems, from many of the experiments, to be more probable. Zaremba's work has been in connection with the influence of the pancreas. He made extracts of the pancreas and mixed these extracts with diphtheria toxin, finding that even in newborn pups the pancreas extract evidently had an antidotal influence upon the toxin. The same influence was observed in relation to the pancreas of young rabbits, guinea-pigs, and calves, and there was no very evident difference between the action of the pancreas of calves a few weeks old and the pancreas of full-grown cattle. He made

several investigations of the human pancreas from adult subjects. The results were negative in every instance. The organ could not be removed from the body for a number of hours after death in any of these instances, and it is quite possible that postmortem changes had destroyed its previous activity. It was found, however, that the pancreas of a boy 4½ years old had a distinctively antidotal influence. The postmortem in this case was carried out about two hours after death, and in several instances it was found that the pancreas of very young children, upon whom postmortems were done almost immediately after death, had a distinctly antidotal effect. In two instances, however, absolutely no influence could be observed. The conclusion which Zaremba reaches is that the pancreas even of extremely young children shows distinctly antidotal influences, but that these may be absent in some conditions, the exact nature and influence of which we do not yet fully understand. [D.L.E.]

2.—Kelling gives a general discussion of the surgery of non-malignant gastric diseases. He ends by directing especial attention to the fact that, in cases of ulcer, and conditions following ulcer, in which proper treatment has been carried out without any satisfactory results, it must be considered that there are certain factors present which prevent the healing of the ulcer or the cure of its sequelæ. He advises careful clinical observation and medical treatment of such cases, but if such practices are of no avail, it is advisable to adopt surgical measures, even though it cannot be determined exactly what the fault is. The danger of hemorrhage, of severe gastritis, of perforation, of carcinomatous change, or of a chronic condition of ill health, is so great that the probability of being able to relieve the condition by surgical means makes such surgical intervention advisable. The dangers of surgery are less than the dangers of the possible complications mentioned, or of protracted under-nourishment. Usually the best operation in such cases is gastroenterostomy. One of the important conditions in which gastroenterostomy should not be postponed too long is in case of ulcers in connection with gastroptosis and atony of the stomach. Internal treatment usually is not very successful in such cases. In some cases it will be found that the ulcer causes no actual stenosis at the pylorus itself, and yet pyloroplasty causes marked improvement. This is probably due to the fact that there is a great deal of swelling or hemorrhage about the ulcer, and that the pyloroplasty in increasing the circumference of the pylorus has decreased the irritation of the ulcer through retention of the food in the pyloric region. Kelling believes that the most important reason that ulcers do not heal readily in women, is that the menstrual losses of blood interfere with a proper nutritive condition. Surgery in such cases is more frequently demanded than in men. As to adhesions, he says that if these interfere with the proper movements of the organ surgery should be undertaken. If they are of acute inflammatory nature they should first be treated medically. Neurosis may be sometimes wisely treated by surgery. In two cases of hysterical vomiting, and in one case of neurasthenic periodic vomiting, Kelling has known gastroenterostomy to be entirely negative in its effects; but in cases of nervous hypersecretion, for instance, surgery may do a great deal of good. As to the treatment of gastroptosis. He states in the first place that the gastroptosis itself is not likely to be satisfactorily and permanently influenced by any operation directly on the stomach or its supports, and unless there is some marked disturbance of motility, or unless the abdominal walls are extremely lax, operation is contraindicated. Of the dangers following operation upon the stomach he first mentions pneumonia, which is an extremely slight danger if the operation is properly carried out. There is always some danger of infection of the peritoneum, but this may be reduced to an extremely low percentage. There is also some danger of the occurrence of a so-called vicious circle of the gastric contents. Proper technic will usually prevent this. The dangers of diarrhea and intestinal ulceration are dependent upon irritation by the extremely acid gastric contents, which are discharged directly into the intestine unneutralized. This may be overcome only if one makes the junction between the stomach and the first portion of the jejunum, whereby a portion of the stomach-contents flows back into the duodenum; in such case a lateral gastroenterostomy should be undertaken, while in cases where the chief object to be accomplished is complete emptying of the stomach, Roux's circular gastroenterostomy should be chosen. [D.L.E.]

3.—The case described is that of a woman who complained of loud borborygmi with a feeling of tension in the gastric region, these symptoms coming on some time after each meal. There was some mental depression and a little reduction of the general health, otherwise there were no distinct changes in the physical condition. Examination of the stomach-contents showed the presence of a peculiar bacillus which had, in brief, the following characteristics: It stained by Gram's; it was facultatively anaerobic and aerobic; it grew rapidly in ordinary media, particularly when the medium contained glucose and milk sugar; it produced much gas, the major portion of the gas consisting of hydrogen and CO_2 ; it produced acid, and grew well in a medium to which acid stomach-contents had been added; it was pathogenic when injected into the peritoneal cavity, but not when introduced into the stomach; it differed from the *Bacillus lactis aerogenes*, from the *Bacillus coli*, and from other organisms which have been described as producing gaseous distention of the stomach and intestines. The symptoms complained of came on about 2 hours after eating, a time when ordinary fermentation could not have occurred; there was no lactic acid present, and no other evidence of ordinary fermentation in the stomach-contents, and the common fermentation bacteria were absent; therefore, the authors conclude that the enormous gas-production which occurred in this patient was due to this microorganism, particularly since the gases produced in the stomach were found to be chiefly hydrogen and CO_2 . 24.—Struppler, after a brief discussion of the various forms of the disease, reports 2 cases of myositis. The first, a man of 39, 2 days before admission to the hospital, had a sudden pain in the left knee, which became severely swollen. Later, other large joints were involved, and large reddish or reddish-brown spots appeared on the legs. There was difficulty in swallowing and some dyspnea. The condition grew rapidly worse, the purpuric eruption extended to other areas, the respiration became more and more affected as a result of edema of the larynx, and finally death occurred before an operation could be performed. At the autopsy the lungs contained pneumonic areas, and there was hemorrhagic myositis in the muscles of the arms and legs. The patient also had acute glossitis. Microscopically the muscles showed acute parenchymatous changes. The heart muscle, however, was not involved; and the spleen was only slightly enlarged. Nevertheless the author believes that the diagnosis must stand as given. It is greatly to be regretted that no mention is made of any bacteriological studies. The second patient, a man of 24, had severe attacks of acute articular rheumatism and scrofula. He was suddenly attacked with severe pain in the left half of the head, which became swollen and soft, there was also swelling in some of the larger joints, pain in the muscles of the calves, but no reddening of the skin. Subsequently another attack occurred on the left side of the head, and there was some erythema of the skin with purpuric eruptions upon the extremities. The diagnosis was made of polymyositis acuta with erythema multiforme. [J.S.]

25.—May, having had occasion to preserve urinary sedi-

ment, employed the method of Gumprecht, that is the addition of a formalin solution to the sediment after the supernatant fluid had been decanted. He found that it was an excellent preservative medium; but that when any considerable quantity of urine was allowed to remain with the sediment, there was a precipitate of round bodies, slightly yellowish, insoluble in almost everything, that occasionally had a somewhat concentric arrangement with lines radiating from the center. A considerable quantity of these gave proportions of nitrogen, hydrogen, and oxygen, corresponding with those of diformaldehyde urea. Further experiments showed that formalin, added to urine combined with a small proportion of the urea present, does form this combination. It is not soluble in water, alcohol, ether, acetic acid, hydrochloric acid, or ammonia, but is soluble in a 25% solution of sulphuric acid (25%) under the influence of heat. It is particularly important, because its presence in the urinary sediment might give rise to errors in diagnosis, and it is, therefore, important when an attempt is made to preserve the urine by Gumprecht's method, to wash the sediment thoroughly with water. [J.S.]

26.—May describes the following method for the demonstration of elastic fibers in the sputum: Equal portions of sputum and 10% of potassium hydrate are mixed and dissolved over a water bath, then centrifugated and the supernatant fluid poured off. About 2 ccm. of Unna's Tánzer orcein solution are added to the sediment, and enough hydrochloric acid to restore the cherry-red color; the tube is then plunged in boiling water, the sediment decolorized with hydrochloric acid and alcohol and again centrifugated. Finally the sediment is examined under the microscope, and the elastic fibers readily recognized on account of the brownish-red violet color. Other fibrous elements are either decolorized, or only faintly tinged. The entire operation requires about half an hour. [J.S.]

27.—Kersbergen has undertaken a careful series of experiments for the purpose of proving the value of the work of Schmidt and his followers. Specimens of the feces were tested for sugar, starch and its derivatives, and for various ferments, particularly invertin. Maltose was very frequently present, even after the specimen had remained six hours in the incubator. It was only persistently absent in one case of carcinoma of the rectum. No effort was made to separate the bacteria and the ferments, although this is possible by means of filtration, or even by the addition of antiseptics. [J.S.]

28.—Grassmann has studied 288 patients suffering from the early stages of syphilis with reference to cardiac and vascular disturbances. Of these 61 were men, and 227 were women. The reason for the excess of women was that these were kept in a hospital under police supervision, whereas the men came and went as they pleased. Sixty-six of these patients, 18 men and 48 women, presented various circulatory anomalies in the course of treatment. Among these changes were bradycardia in one woman, arrhythmia in 6 cases without other changes, and in 3 cases with alteration in the heart-sounds. These symptoms occurred both in recent cases and in those with relapses. In 10 cases there was arrhythmia and increased frequency of the pulse. In a few cases there was simply increased frequency without other disturbance. In one of these cases the increased frequency lasted for more than 10 weeks; many of them, however were purely temporary conditions. In many of the cases there was increase in the force of the second pulmonic sound, but in one only of the second aortic sound. In 14 cases there were distinct murmurs, or impurities of the heart's sounds; in 6 of these cases the murmurs disappeared completely with recovery from the disease. These murmurs were probably chiefly functional because they were heard either at the base of the heart, or over the tricuspid area, and were systolic in time. Of the subjective disturbances, the most important was palpitation. In discussing these cases, Grassmann states that he does not believe that accentuation of the second pulmonic sound is always associated with hypertrophy of the right ventricle. He also discusses 32 cases in which systolic murmurs were heard at the beginning of treatment, that were possibly the result of nervous or muscular disturbances of the heart itself. In 9 of these cases no impairment ensued in the heart symptoms. In 17 the symptoms grew worse during the employment of mercury, but in the majority the murmurs were distinctly functional in type.

The second pulmonic tone, however, was often increased without distinct enlargement of the right ventricle. In 3 of the cases apparently, a mitral insufficiency was in the course of development. [J.S.]

29.—Köster in continuation of his valuable article upon facial paralysis, as the result of the study of his cases, and their comparison with others recorded in the literature, reaches the following conclusions which we give in full: First, if the lesion is peripheral, and situated below the stylomastoid foramen, or as far up as the point of branching of the chorda, it can be recognized by the fact that all other nervous symptoms are absent, with the exception of the unavoidable disturbance of perspiration and the pure motor paralysis. Second, if the lesion is situated above the branching of the chorda there will be, in addition to the disturbance of motion and perspiration, also some disturbance of taste, and frequently alterations in the quantity of saliva secreted. Third, if the lesion is situated in the geniculate ganglion, there will be, in addition to the above symptoms, disturbance of the secretion of tears, which is permanent, and some disturbance of hearing, indicating a simultaneous lesion of the acusticus, which is not always constant. Fourth, if the lesion is situated above the geniculate ganglion, and before the entrance of the nerve into the brain, all the symptoms above enumerated are present with the exception of loss of taste. Fifth, if the lesion has destroyed the facial nucleus and the immediate neighboring tissue the same disturbances, as above described, will be present, and the diagnosis can only be made on account of the presence of other lesions indicating medullary involvement (homo- or contralateral paralysis of the extremities, imperative laughing or weeping). Lesions restricted to the facial nucleus, especially if congenital, produce only motor paralysis with a slight disturbance of the secretion of perspiration. Köster, however, having seen only 2 such cases, both of which were bilateral, is not quite positive regarding their localization. In a second part of the paper he reports a number of experiments made upon dogs, cats, and monkeys which cannot be fully described here. A few of the interesting results are, that in dogs, cats, and monkeys the subcutaneous malar nerve has no anatomical connection with the lachrymal nerve, stimulation of which does not alter the secretion of tears. In cats the chorda tympani contains sensory fibers. The secretory fibers of the submaxillary and sublingual glands in apes certainly pass downward and through the facial nerve, thus confirming the supposition that the same is true of human beings. After division of the facial nerve, degenerated fibers are never observed in the lachrymal nerve, indicating that these fibers do not pass through the facial. As this contradicts the partial observations made upon men, Köster believes that there must be some difference in the innervation of this gland. [J.S.]

30.—Schiffmacher reports the case of a man of 42, who for some years had had an itching eruption on the abdomen. This consisted of large blotches of a bluish brown-red color, with elevated hard, infiltrated plaques, that almost had the appearance of tumors. These were scattered, quite irregular, and upon their surface showed slight desquamation. There were also a few patches of eczema and erythema. The inguinal glands were swollen, but otherwise the patient was normal. Microscopically, an excised portion of the skin showed cellular infiltration in the papillary bodies, considerable hyperplasia of the rete Malpighii, which sent projections into the surrounding tissues; otherwise, there was nothing characteristic. Although bacteriological studies were negative, Schiffmacher has no doubt that this was a case of mykosis fungoides. The patient was treated with ascending doses of arsenic, given hypodermatically, which in the course of several weeks apparently produced almost complete cure. [J.S.]

31.—Jürgensen reports a case of carcinoma of the stomach that had undergone degenerative changes, and in which free hydrochloric acid was present for a long time. There was considerable obstruction at the pylorus and, as a result, the gradual inspissation of the tissues, with diminution in the quantity of urine. There were also some curious disturbances of the nerves, apparently depending upon the quantity of urine excreted, such as myosis, loss of reflexes, and some intellectual dulness. Towards the end there was moderate elevation of temperature. At the autopsy there was found a gangrenous ulcerating carcinoma of the pyloric region,

with moderate dilatation of the stomach. There was no satisfactory explanation of the persistence of free hydrochloric acid. [J.S.]

1. Alcoholism in Childhood. DR. DELOBEL.
2. A Case of Appendicitis with Abscess Formation and Rupture into the Bladder; Recovery. PEREZ ALLAN.
3. Adenoid Growths. A Statistical Study of the Cases Treated in La Clinique des Enfants Malades, 1899-1900. Clinical and Therapeutic Considerations. HENRI CUVILLIER.
4. Treatment of Acute Mucous and Dysenteriform Colitis by the Sulfate of Soda. M. AVIRAGNET.

1.—Delobel contributes 7 cases to the literature of **alcoholism in infancy and childhood**. He calls attention to the fact that the condition is much more common than is credited. In the first period of life the intoxication is brought about through the milk of the nurse or mother, who are generally in total ignorance of their deed. The child too, is an unconscious agent. Later, the taste having been developed, the child becomes eager to get liquor by every possible means. Here parents are frequently criminally responsible in letting the child take sips of liquor "from father's glass" and telling their children that it is manly to drink and will make them big and strong. Alcohol has not been found chemically in the milk of intemperate lactating women, but the effects upon the child prove the toxic property of such milk. The susceptible child shows in a brief space of time the profound systemic changes of chronic alcoholism which in the adult takes vastly longer to produce. A number of French authorities are quoted upon the effect of alcohol in children. In general, it may be said that alcohol produces convulsions in breast-fed infants. This is not always the case. Sometimes the symptoms developed are a fretful, highly nervous state, the child constantly crying and sleeping but little. This will in some cases be followed by digestive disturbances and marked cachexia. The body weight may be in excess and the child show signs of over-nutrition, but this is generally followed by progressive debility and wasting. In this type convulsions do not occur; on the other hand the child is in a constant state of agitation, and suffers from insomnia. The pulse is frequent and feeble and the eyes brilliant, the cheek prominences are red, there is some pyrexia and the child has an air of hebetude; there is excessive thirst, while at the breast he sucks vigorously and keeps up the motions of suction in the brief intervals between the constant crying for food. Death follows unless the cause be removed. In the first two of Delobel's cases, the children had recurring **convulsions** easily controlled by **tepid** baths. In each case the wet-nurse was found to be intemperate and recovery followed her dismissal. In the third case there was no convulsions, but the type was one of excess in body-weight with the accompanying symptoms detailed above, and was succeeded by a grave cachexia in which recovery seemed doubtful. Removal of the cause—another intemperate wet-nurse—marked the beginning of convalescence. In another case seen by the author the child was in a pitifully nervous state due to its having been given **coffee** with **brandy**, because the child seemed so weak and sickly. His advice was not heeded and the case is not reported further. The **fifth report** is that of a child of 5 years who suffered from **alcoholic cirrhosis** with accompanying **ascites** (which was several times tapped) and in which death resulted. The child had been in the habit of becoming frequently intoxicated upon a mixture of coffee and alcohol. He presented all the appearances of a confirmed dipsomaniac. His sixth case was one of an **acute state of alcoholic coma** in a child of 4 years who lived aboard a vessel with intemperate parents. The child had secured and partly emptied a bottle of rum. His last case was one of **acute alcoholism** in a girl of 7 years. She was a confirmed inebriate—and grew up to be a prostitute who served her term in prison. In conclusion Delobel urges that the criminal ignorance of such children's parents be punished and that proper penal laws and an effective system of medical inspection be instituted. He believes that education is the surest method of gradually

eradicating the evil. The physician must be on the alert to discover possible alcoholism in the mother or nurse, and to remember how much secret and totally unsuspected drinking is done. [T.L.C.]

2.—Perez Allen presents the report of a case of **appendicitis with rupture of abscess into the bladder**. There being no doubt as to the diagnosis of appendicitis, opium and bismuth were administered freely. After a few days a palpable tumor was present in the right inguinal region. Operation does not seem to have been considered. The abscess finally ruptured into the bladder, and symptoms of pyuria appeared. The viscus was frequently flushed. After a few days the urine became normal. One of the sequelae of the case was a **double orchitis**, from which the patient made prompt recovery. [T.L.C.]

3.—Cuvillier has reported that of 2019 cases of **adenoid growths** treated in his clinic, La Clinique des Enfants Malades, 1214 were of the respiratory type; 75 of the auricular type and 730 of mixed form. He details the symptoms to which these growths give rise by their mechanical obstruction, and as the cause of bacterial infection, etc. He points out the necessity of thorough examination of all cases, and particularly urges that the condition be treated properly and not left to run its course to the child's detriment. He divides his treatment conveniently into prophylactic, medical and surgical. Prophylactic treatment should be instituted in those cases which present predisposition to lymphatic enlargements. It should consist of general tonics and local antiseptics. He mentions among the latter instillations of oil and insufflations of medicated powders. He prefers mentholated oil (1:50) on account of its astringent and valuable antiseptic properties. In cases where this is not well tolerated, he recommends a combination of sterilized olive oil with resorcin (1 part to 25 of the oil). The instillation should be made two or three times a day. As another application, borated vaseline or mentholated vaseline is recommended. An excellent powder may be employed consisting of menthol 10 c. g., boric acid and talcum, of each 5 grams. The nasal irrigation may be prescribed with the above treatment, but the author points out very wisely the possibility of damage by this method and shows the necessity of having the canal freely open and using but slight force in the douching. Explicit directions are given as to the manner of using the douche. The quantity should not be more than 20 ccm. the fluid, preferably a boric acid solution. When the **adenoids** are actually present, the author directs that medical treatment should consist of an application of iodine with glycerin, 1:50. This will greatly reduce the size of the growths and act favorably upon the catarrhal condition. This treatment is merely palliative and surgical measures are our only means to effect a cure. The operation which is described must be conducted with careful antiseptic measures, both preparatory to and succeeding the operation. An anesthetic—ether or bromid of ethyl—may be employed. Adenoids carefully removed do not recur and radical operation is insisted upon. [T.L.C.]

4.—**Acute colitis** constitutes a clinical type which is distinct from gastroenteritis. Acute colitis may be primary or secondary. In the latter case it succeeds a gastroenteritis or appears in the course of one of the infectious diseases. The pathology of colitis is identical with that of gastroenteritis. Colitis may be divided into the gangrenous form with glairy or mucous secretions; and a second variety, the dysenteriform. These may appear as a mild type with fever, or a severe type with the advent of the algid state. The symptoms of the second variety are akin to true dysentery. The pathologic changes occurring in dysentery, however, are more destructive. Regarding, as Aviragnet does, that the two dysenteric conditions are similarly caused, he treats them identically. His method is to place the patient at rest in bed; to relieve the abdominal pain by cataplasms or hot or cold applications. He disbelieves in the use of lavage of the large intestine, arguing that distention of the inflamed bowel augments the pains, and possibly the inflammatory process. He diminishes the rectal tenesmus with small injections of weak solutions of laudanum, and advises this treatment rather than suppositories. To combat the inflammatory process, he discusses the use of injections of ipecac, borax, hyposulfite of soda, and various suppositories. He believes these means should be rejected in the acute form of colitis, because they are insufficient, save in very benign

cases, and because they add to the irritability of the bowel, and may increase the inflammation and pain. He discusses the administration of calomel and ipecac by the mouth and then takes up the treatment with sulfate of soda, from the use of which he claims remarkable curative results. He prescribes 10 to 15 grams the first day (administered in a glass of sweetened water). This dose is slightly aperient, and especially useful when stomach irritability is pronounced. Small doses are given the day following. For example, to a child of from 12 to 14 months, 5 grams. The dose may be varied, and the administration continued for several days. The blood rapidly disappears from the stools, the rectal tenesmus disappears, and diarrhea soon ceases. The warm bath may be used as a valuable adjuvant to this treatment. He does not claim the method of treatment a new one, but wants to emphasize its utility. [T.L.C.]

Annales de la Société Belge de Chirurgie.

December, 1900. [8me Année, No. 10.]

1. Intestinal Obstruction, Due to Lateral Pinching of the Intestine. SNEYERS.
2. Invagination of the Small Intestine in the Rectum, with Strangulation. LAUWERS.
3. A Suppurating Cyst of the Ovary. LEBESGUE.
4. Luxation of the Median Nerve. DEPAGE.
5. Huge Double Inguinal Hernia. DELETREZ.
6. Frontal Autoplasty. DEPAGE.
7. Pyemia of Otic Origin. VINCE.
8. Elephantiasis of the Vulva. DELETREZ.

1.—Sneyers reports two cases of **lateral pinching of the intestine**, both occurring in women, under Gimbernat's ligament. In both cases the condition was correctly diagnosed, and both recovered after operation. The constriction occurs generally at the internal ring, and very quickly causes strangulation. Pain and swelling at the internal ring, with frequent stools, or flatulence, should suggest it. Operation is indicated at once, the bowel sinking into place; or if it is gangrenous, resection will be necessary, as in hernia operations. Warm compresses applied to the affected bowel will soon show whether circulation has been reestablished or not. [M.O.]

2.—A woman of 74 years had shown signs of internal strangulation for some days. For 3 years she had had prolapse of the rectum, which had previously been easily reduced. Four days before there was relapse, with great pain, the pain persisting even after reduction. Fecal vomiting followed, and rectal examination discovered a **tumor in the rectum**. Laparotomy was performed, and 60 cm. of the small intestine found invaginated in the rectum, gangrenous but not perforated. The whole mass bulged into the peritoneum, which made the sac for the hernia. The gangrenous intestine was removed and the ends sutured. Drainage was left in. Eleven days later two fecal fistulae were discovered and sutured, after which the patient recovered, in spite of her age. [M.O.]

3.—A woman, aged 41, had had pain deep in her pelvis, off and on during a pregnancy. After her child was born a tumor was discovered on the right side of the abdomen. The pain returned for a month and then disappeared. Five months later, as the mass was very large, laparotomy was performed and a multilocular cyst of the right ovary found, which when punctured emitted a thick, purulent fluid, containing several pyogenic micrococci. There were many adhesions between the intestines and the cyst. The patient died suddenly 3 days later. Lebesgue thinks that the cyst became purulent, in the absence of colon bacilli, from the influence of the pregnancy. [M.O.]

4.—Depage presented a child of 14, who had dislocated his right elbow 3 months before. This was at once reduced, and kept immobilized a week, after which the arm was moved under chloroform, but **paralysis of the muscles** supplied by the median nerve, and loss of feeling in the forearm persisted. Depage operated at the elbow, but could not find the median nerve. A month later he operated again and found the nerve behind the olecranon. This was then dissected out and replaced on the other side of the process. Since then movement of the forearm has improved with electricity, but the loss of sensibility remains about the same. [M.O.]

5.—Deletrez reports a case of huge **double inguinal hernia**, which had existed 5 years in a man of 60, cured by Bassini's operation. Photographs before and after operation are given. [M.O.]

6.—Depage presented a patient, aged 74 years, who had had a **rodent ulcer** upon the center of his forehead. Depage had made flaps from the forehead, cutting on either side of the central ulcer, leaving them attached below. These he sutured together over the ulcer, and in the two denuded spots above, on each side, he planted skin by Thiersch's method. Now there are but three scars, the tiny median one where the flaps joined, and the two outer ones. It is needless to mention that the patient was bald. [M.O.]

7.—A boy of 8 years, with **double suppurative otitis**, complained of severe headache with fever and delirium. Mastoid operation was done, but nothing was found. During the next week signs of peritonitis developed and **laparotomy** was performed. There were no signs of peritonitis, yet the temperature continued hectic. A few days later tenderness was noted in the dorsolumbar spine, and the bowels and bladder were emptied involuntarily. Then an abscess appeared over the right external malleolus, and was opened. Next an abscess appeared about the trochanter of the right femur, which was also incised and drained. A week later another abscess appeared in the left hip, which was at once opened. During the succeeding month all the abscesses improved, and a month later the boy was well. Recovery after such severe pyemic infection seems remarkable. [M.O.]

8.—Deletrez presented a case of **elephantiasis** of the vulva, in a woman of 50 years, who had convulsions as an infant, epilepsy later, was of but slight intelligence, had strabismus, and ankylosis of both hips. The growth began 12 years ago. It is now 35 cm. in its anteroposterior diameter; laterally, 24 cm. Its weight is 5½ kilograms. The surface of the tumor is covered with nodes and hair. There seem to be no changes in the skin. He expects to operate. Others present disagreed with the diagnosis, believing it to be a fibrolipoma. A photograph of the tumor is given. [M.O.]

Journal des Praticiens.

January 5, 1901. [15me Année, No. 1.]

1. A Case of Mucous Colitis with Hemorrhage. TRIBOULET.
2. The Preparations of Copper for Internal Use. LIÉGEOIS.

1.—Triboulet gives the minute details of a case of enteritis, at first diagnosed dysentery. The acute attack over, but little blood or mucus appeared in the bowel-movements for a month. Then occurred daily attacks of colic, followed by mucous stools, with a great deal of blood, both bright and dark-red, mixed. During 50 or 60 days, the patient, a young girl of 20, lost 40 to 80 grams of blood daily. Under high injections of nitrate of silver the condition disappeared. [M.O.]

2.—Liégeois enumerates 7 preparations of copper which can be given internally, giving their doses and indications, and quoting authors who have used them successfully. [M.O.]

January 12, 1901. [15me Année, No. 2.]

1. Ano-rectal Fistula as a Premonitory Sign of Phthisis. ERNEST BARIÉ.
2. Abortion from a Medico-Legal Standpoint. PROFESSOR BROUARDEL.
3. The Heavy Metals in the Treatment of Anemia. PROFESSOR CERVELLO.

1.—Recent researches show that about 5% of all phthisical patients have fistula in ano. Tubercle bacilli are generally found in the pus, alone, or with staphylococci and streptococci. Though they occur, as a rule, with or after the pulmonary lesion, **they may even precede the phthisis**, by from 4 to 18 years. Barié reports 5 such cases, 2 of which had their exciting cause a traumatism. [M.O.]

2.—In performing an autopsy upon a woman who is supposed to have attempted abortion, search must be made for the embryo, or pieces of it; or for the placenta; or if the uterus is empty, the thickness of its walls must be measured, and the insertion of the placenta sought, as this can be recognized up to the tenth day after the expulsion of the embryo.

This is possible even later, if the uterus is kept in 90% alcohol. The examination of the ovaries is of only relative importance, as no positive signs exist there. Stains of meconium, if found, will prove the abortion. If an instrument has been used to cause abortion, traces of the damage done by it will be seen. This is especially true when the uterus has been perforated. Brouardel advises his students, should any one of them be called upon to do an autopsy upon a suspicious case, in which a physician is accused of having performed abortion, to ask that the accused physician be present at the autopsy to explain what he had done, and why he had done it; and then from the result of the autopsy it can soon be decided whether the accused is guilty or not. [M.O.]

3.—Cervello reviews the work done on this subject and reports some experiments upon dogs and chickens, in which **copper, zinc, manganese, and mercury acted like iron** in cases of **anemia** and chlorosis. He believes that under their use the hemoglobin in human blood will readily increase. [M.O.]

January 19, 1901. [15me Année, No. 3.]

1. Alopecia or Pseudoalopecia in Syphilis. ALFRED FOURNIER.
2. The Effect of Gout and Rheumatism upon the Eye. A. TROUSSEAU.
3. Headache Treated by Acetate of Ammonium. LIÉGEOIS.

1.—It is not rare that circumscribed areas of **absolute alopecia** occur in the scalp or beard in **syphilis**. They are small and few, well circumscribed, lasting a short time, but recurring often. This appears later on in syphilis, and is very different from that general thinning of the hair seen early in the disease, which never returns. Fournier concludes that it may be a manifestation of the syphilis, or a parasymphilitic result of the syphilis. Time may prove which. [M.O.]

2.—Trousseau notes that symptoms of **iritis** and **corneal sclerosis** may be the **first signs of gout or rheumatism** to appear in the descendants of gouty or rheumatic families. He reports a number of cases to illustrate this occurrence. He suggests treating these cases for gout or rheumatism at once. [M.O.]

3.—Headache after meals with flushes of heat, in neurasthenics, is unaffected by ammonium acetate. Nor has it any effect upon emotional headache with palpitation of the temporal arteries. But in the early morning headache of **neurasthenia** or **chlorosis**, **liquid acetate of ammonium** works very well in one dose of 6 grams. Liégeois has also used this successfully in pseudoangina pectoris, in ophthalmic migraine, and in dysmenorrhea, in nervous subjects. [M.O.]

Relations Between Malaria and General Paralysis.—From a study of 8 cases Marandon de Montyel (*Revue de Médecine*, November 10, 1900) concludes that acute **malaria** may produce progressive **general paralysis** or general pseudoparalysis in those who are predisposed. Chronic malaria, also, may produce progressive general paralysis in those who are predisposed, and probably may induce it in those who are not predisposed. Acute malaria may cause precocious progressive general paralysis in those who are predisposed. Malarial manifestations supervene, in the course of progressive general paralysis they are often complicated by cerebral congestions which aggravate the brain disease and hasten its evolution. The progressive general paralysis that develops under the influence of acute or chronic malaria nearly always has a rapid evolution. The relations of the two diseases are incontestable, although the one does not often manifest itself as a cause of the other. The symptomatology and the pathologic anatomy of general paralysis of malarial origin presents no special characteristics. The histories of the 8 cases are given. Of the patients, in addition to malarial infection 4 presented a history of syphilis combined with family history of neuroses; 1 gave a history of cerebral trauma; 1 presented a family history of nervous disease; and 1 had convulsions in infancy and suffered from nocturnal enuresis during childhood. One patient only gave a history free from hereditary taint of nervous disease, from syphilis, and from trauma. [J.M.S.]

Practical Therapeutics.

For Constipation with Flatulence.—Illoway (*New Orleans Medical and Surgical Journal*) recommends:

R.—Extract colocynth. co..... $\frac{1}{2}$ grain.
Terebinth. Veneta..... 1 grain.
Pulv. aloes, socot..... $1\frac{1}{2}$ grain.
Ext. nucis vomic..... $\frac{1}{2}$ grain.
Ext. hyoscyami (English)..... 1 grain.

M. ft. mass. et ft. pillul. No. 1. Sig.—One pill 2 or 3 times a day.

Treatment of Freckles.—Jamison (*British Medical Journal*) states: "Certain skins exhibit an exaggerated sensitiveness to light, but to only one of the methods in which such react will reference be made at present. Some individuals, particularly those with reddish hair, freckle readily during the brighter part of the year. This impressibility may be congenital, the result of changes due to age, or acquired as the consequence of excessive exposure to intense radiation. There can be little doubt that these freckles are an effort on the part of nature to protect areas which are from some cause more than usually delicate, to impart rapidly to limited spots the same safeguard which the progress of the ages has given to the darker races of humanity. The researches of Bowles have proved that it is the chemical rays which are thus active, and though their effects are most pronounced on uncovered parts, they are not restricted to these. They in this respect correspond to the x-rays, since freckles are met with on portions of the body on which the sunlight never impinges directly for any length of time, if at all. The most remarkable example of this susceptibility occurs in xeroderma pigmentosum. Not only have we intense freckling, but dryness and hyperkeratosis, at first diffuse, after a time taking on a warty and then a carcinomatous degeneration. Unna has suggested that by due protection from the chemical rays the freckling might be modified in this disease, the further malignant changes postponed or arrested, and amelioration, if not cure, obtained. A case of this kind has been under my care for two years and a half, and in it we have been able to check the advance almost perfectly. An ointment stained brown by the addition of raw umber has been pretty constantly applied to the face, a dark brown veil worn whenever the child (now six) has gone out, and the warts on their earliest appearance treated with salicylic collodion. In this way fairly perfect rest has been obtained for the abnormally tender skin."

Prevention of Gastric Fermentation.—Ewald (*New Orleans Medical and Surgical Journal*) recommends:

R.—Resorcin resubl..... 50 (75 grains.)
Bismuth salicyl. }
Pulv. rad. rhei. } of each100 (150 grains.)
Natr. sulph. }
Sacchar. lact.....150 (250 grains.)

M. Sig.—Make a powder; $\frac{1}{2}$ teaspoonful twice daily.

Contribution to the Study of Iodoform Poisoning.—Anschütz (*Beiträge zur klin. Chir.*, Bd. xxviii, H. 1, p. 233) reports a case of iodoform poisoning in a man 30 years of age after a third injection of 100 ccm. of a 10% iodoform glycerin emulsion into a psoas abscess. The symptoms in this case were as follows: Slight vomiting during the first day after the injection, a progressive somnolence beginning on the ninth day, a widely disseminated acne eruption, desquamation of the buccal mucous membrane, crust formation in the nose, agglutination of the eyelids, followed by increase in the reflexes of the lower extremities, and stertorous respiration. Large quantities of iodoform were found in the urine. In spite of the evacuation of the iodoform emulsion by means of saline irrigation, death followed after 2 days. The whole clinical picture presented a grave case of iodoform intoxication which heretofore had only been observed experimentally upon animals. The author considered the cause of this rare symptom-complex as due to the caseation of both suprarenal capsules, which was substantiated postmortem upon micro-

scopic examination. There were no symptoms of Addison's disease.

Therapy of Fibrinous Rhinitis.—F. Peltesohn (*Therapeutische Monatshefte*, September, 1900) recommends a solution of cyanide of mercury 0, 02: 50, for dissolving the membrane. The solution is applied with cotton on a probe and applied alternately to each nostril for one hour at a time. He reports astonishing results.

Amenorrhœa.—Bloom (*Gazette hebdomadaire de Méd. et de Chir.*, April 1, 1900) recommends the following for amenorrhœa:

R.—Strychnin, sulf.....0.002.
Acid oxal0.01.
Ferr. peptonat. } of each0.1.
Mangan. lact. }
Extract colocynth. comp0.03.

M. Sig.—One powder, three times daily, after meals.

The Therapy of Hemoptysis in Tuberculosis.—A. Hecht (*Therapeutische Monatshefte*, 1900, No. 10) has employed Huchard's pills (ergotin, quin sulphate, pulv. fol. digitalis, extr. hyoscyam., of each 0.1) in a number of cases of hemoptysis in tuberculosis. In all cases, upon systematic application of the remedy the hemoptysis was checked. Two cases that had withstood the customary remedies were checked after employment of these pills. The author believes that the hemostasis is not to be attributed to the ergotin, but to the quinin reinforced by the digitalis.

For Bronchial Asthma.—Goldmann (*Wiener med. Wochenschrift*, 1899, No. 43) reports 43 favorable results with Neumeier's asthma powder which consists of stramonium, lobelia, potassium nitrate, potassium iodid and sodium nitrite. There are no injurious manifestations. A teaspoonful of the powder is placed in a saucer, ignited, and the fumes slowly inhaled. The influence of the remedy is a local one, and it has an analgesic effect upon the mucous membrane.

Gargles in Acute Tonsillitis:—

R.—Tinct. belladonnæ..... $\frac{1}{2}$ dram.
Glycerini.....2 $\frac{1}{2}$ drams.
Decoct. althææ. enough to make6 ounces.

M. Sig.—Use as a gargle two or three times daily.—Schnitzler.

R.—Tinct. aconiti.....8 minims.
Syrupi aurantii.....3 drams.
Aquæ destil. enough to make.....2 ounces.

M. Sig.—One teaspoonful every two hours for a child of 4.
—J. A. M. A.

FOR LOCAL APPLICATION.

As a local application the following may be found of service in such cases:

R.—Iodin.....3 grains.
Potassii iodidi1 dram.
Glycerini enough to make1 ounce.

M. Sig.—Apply locally to the tonsils three times a day by means of a brush or cotton swab.—*Medical Fortnightly*.

AT COMMENCEMENT OF ATTACK.

R.—Tinct. ferri perchloridi.....1 dram.
Glycerini2 ounces.

M. Sig.—One teaspoonful every two hours.

Iron given as in the above form without the addition of water is by some authors regarded as a specific in treatment of tonsillitis, believing that it relieves the pain, shortens the duration and lessens the congestion, as it has a local as well as a systemic effect.—*Medical Fortnightly*.

Transitory Glycosuria in a Case of Acute Morphin Poisoning.—E. Adler (*Prager med. Wochenschrift*, 1900, No. 28) reports a case of transitory glycosuria in a woman, 20 years of age, who had taken about 10 cm. of a 5% morphin-solution. Examination of the urine showed on the day following the poisoning 0.7% of grape sugar, of which hardly an appreciable trace was left on the second day. The patient recovered on the third day. Pentoses were not found in the urine.

CASE OF BLINDNESS FROM SYMPATHETIC OPHTHALMITIS, COMPLICATED WITH SECONDARY GLAUCOMA. RESTORATION OF VISION BY TWO IRIDECTOMIES, ONE WITH EXTRACTION OF LENS, AN IRIDOCYSTECTOMY, AND TYRRELL'S OPERATION OF DRILLING.*

By CHARLES A. OLIVER, A.M., M.D.

of Philadelphia, Pa., U. S. A.

Attending Surgeon to Wills' Eye Hospital; Ophthalmic Surgeon to the Philadelphia Hospital.

Sixty years ago Frederick Tyrrell, at that time Senior Surgeon to the Royal London Ophthalmic Hospital and Surgeon to St. Thomas' Hospital, London, England, wrote these words:¹

"Of the Operation of Drilling. There are many cases in which capsular or capsulo-lenticular cataract is produced by the extension of inflammation from the iris to the capsule. . . .

"In such cases the operation of extraction ought not to be attempted; because the adhesions between the iris and anterior part of the capsule of the lens, make it extremely difficult to get out the lens, after the section of the cornea is made; it cannot be accomplished without much violence; and, when effected, is most likely to excite deep-seated inflammation, which would be fatal to the organ; such has been the unfortunate result of the operation of extraction in nearly all cases of this kind in which I have known it to be performed.

"Some years since, the practice at the Ophthalmic Hospital, in the treatment of these cases, was to divide the iris and lens at the same time, by Maunoir's scissors, so as to form an artificial pupil, and expose the lens to the influence of the aqueous fluid. . . . The result of this practice was, however, so very unsuccessful, that I dreaded to undertake it; and, by careful observation, I had good reason to suspect that a great deal of the mischief which followed the operation, and proved fatal to the eye, resulted from the pressure and irritation produced by the divided portions of the crystalline lens, which were usually displaced by the operation.

"After much careful consideration of the subject, I felt satisfied that a much better result might be obtained by a modification of Mr. Saunders's operation for solution, by which the lens might be got rid of; and that, subsequently, Maunoir's operation might be performed with much less risk.

"The plan I adopted, and have since continued, is as follows:

"The patient being placed as if to undergo the anterior operation for solution, I have passed a very fine straight needle through the cornea at the outer part; and, then, directing the point to the anterior capsule of the lens close to the inner margin of the pupil (taking care not to injure the iris) and causing the instrument to penetrate the capsule, and enter the substance of the lens to the extent of about one-sixteenth of an inch, I have rotated the handle of the needle between the forefinger and thumb, so as to make the point act as a drill; and having secured an opening more free than could be effected by a simple puncture, then I have withdrawn the needle.

"By using a very fine straight needle, of uniform thickness, and by introducing it a little obliquely through the cornea I have frequently performed this operation, without the loss of a single drop of aqueous humor; and I have rarely found it produce any inflammation.

"According to the degree of absorption or solution, I have usually repeated this operation, every 3, 4, or 5 weeks; and have been careful to puncture the opaque capsule in a fresh place, at each operation; and this has generally enabled me so far to weaken or detach the portion of the capsule, occu-

pying the site of the pupil, that it has been easily displaced when the lens has become dissolved.

"The extent of the loss of lens may be ascertained by two means: first, the increase in size in the anterior chamber; secondly, by the resistance offered to the point of the needle; for as long as much of the lens remains, the operator may feel resistance to the point of the instrument; whereas, the capsule alone can hardly be felt.

"I think, upon the average, that I have had to repeat the operation seven or eight times before I have been satisfied that the lens has been removed; consequently the cure has been extremely tedious; but as the plan incurs very little risk, and does not confine the patient for more than two or three days after each operation, there can be no further objection to it than the slowness of its effects, which is more than counterbalanced by the success of the treatment.

"I have operated upon a considerable number of these cases by drilling; and have good reason to be satisfied with the result of the operation; in no instance has it produced inflammation of importance; and, out of the few cases in which it has failed to restore vision, I believe that the sensibility of the retina had been previously and permanently injured; for I succeeded in getting rid of the cataract, and in clearing the pupil to a sufficient extent to afford good vision, provided that the retina had retained sufficient power. It is impossible to decide upon the condition of the retina before operation; excepting so far as regards perception of light, without which the treatment should not be adopted.

"The operation is adapted to all cases of this class, both in young and old persons; for I believe generally that the lens is not opaque, but retains the ordinary consistence; and even when it is opaque in elderly persons in connection with and in consequence of the disease in the capsule, that it has not the hard character of the ordinary cataract.

"In most of these cases which I have operated upon by drilling I have been able to effect all I could desire by the fine needle only; but in a few instances I have been obliged, eventually, to make an artificial pupil by Maunoir's plan of operation; being unable to clear a sufficient space in the natural pupil to afford useful vision; and these operations for artificial pupil have been generally successful; proving that I had formed a correct opinion of the principal cause of failure in the cases submitted to Maunoir's operation whilst the lens remained."

This most graphic description is followed by the clinical histories of several cases occurring during the years 1836 to 1840. In all, there were the sequelae of gross inflammation in the anterior segment of one or both eyes.² In each one the procedure was tried with successful results.

Having had a favorable individual experience with the more recently devised operation of Critchett and Story³ for the laceration of the lens capsule and the evacuation of the lenticular contents in two cases of sympathetic ophthalmitis, which had been considered as irremediably blind, and being aware of Tyrrell's much earlier plan of drilling in cases of capsular or capsulolenticular cataract, induced me to try the latter operation upon a case of blindness from a complicated type of sympathetic disease which seemed to be peculiarly appropriate for the procedure.

As in Tyrrell's method, and unlike the Critchett-Story plan in sympathetic cases of two needles, I limited my instruments to but one, obtaining the capsular incision and producing the evacuation of the remaining lenticular contents by means of a fine, straight needle of the pattern described by Tyrrell.⁴

The result of a permanent $\frac{1}{3}$ of normal vision ($\frac{5}{18}$)

* From the description, it is probable that 1 or 2 of these cases were sympathetic in character.

¹ Critchett, Royal London Ophthalmic Hospital Reports, x, 2. Story: Transactions of the Royal Academy of Medicine, Ireland, 1880-1891.

² On Plate IX, in Tyrrell's work, the author figures the shapes and the sizes of the two forms of Saunders's needle he used; the one cutting only at the point, and the other cutting on each edge to the shaft. The latter pattern of instrument was the one I employed.

in quite a large and well-shaped field, in a quiet and comfortable eye, was much more than I dared to expect in a case of this type of ocular disease.

Briefly, the history of the patient is as follows: On March 16, 1899, I received the accompanying note from Dr. Walter Lathrop, superintendent and surgeon of the State Hospital for Injured Persons of the Middle Coal Field of Pennsylvania, at Hazleton, Pa. "I have a young man here who lost his left eye. He had a piece of steel imbedded in the lens; I enucleated the eye, but the right one was already affected sympathetically. It was 15 weeks from the time of injury till I first saw him. . . . I feel as though he would lose the sight of the right eye. He has posterior adhesion of iris now, and some haziness of vision. . . . Will you take him at Wills' Eye Hospital for a few weeks and do what you can for him? . . ."

One week later, the patient, a 27-year old laborer, reported to my clinical service at the hospital. He stated that his left eye had been struck with a piece of steel some 6 months previously, and that in spite of treatment the eye became blind in 3 months' time. Dr. Lathrop, who brought him to me, told me that when he saw the patient for the first time on the 28th of January, 1899, he had found the injured eyeball so sore and the fellow-eye so irritable that he immediately enucleated the offending organ. Examination of the removed eye by him revealed the presence of a piece of steel imbedded in the ciliary body. Within a week's time after the operation, the right eye became violently inflamed. Since then, in spite of several exacerbations, the gross signs of inflammation in the eye had been kept in abeyance, though unfortunately with an ever-decreasing vision. The treatment employed consisted in the free use of boric-acid flushing and atropin instillations locally, combined with the internal administration of quinin.

When I first saw him, there were all the signs of a pronounced sympathetic iridocyclitis and iridocapsulitis. Marked ciliary injection existed. The iris, which had been originally light blue in color, had become greenish and metallic in tint. Its tissues were thickened, indrawn, and degenerate in many places. The pupil, which was undilated, was almost completely surrounded with rather dense and firm posterior synechia. Dense capsular spots and areas of newly formed connective tissue were plainly distinguishable in the remaining pupillary space. Intraocular tension was somewhat diminished, and slight tenderness in the ciliary region could be obtained by pronounced palpation. Vision was lessened to $\frac{1}{8}$ of normal. The fields of vision for green, red, and white were concentrically reduced to about $\frac{1}{2}$ of their relative areas. No scotomata or peripheral indentations could be found.

I at once admitted him into the wards of the hospital, and, in addition to his former treatment, ordered the employment of hot stupes with tri-weekly injections of solutions of chlorid of sodium deeply into the subconjunctival tissues.

As a result of 3 weeks' trial of this treatment, the eye became much more quiet. Free communication between the anterior and posterior chambers established itself through the irregularly, though but slightly enlarged pupillary area. The iris became healthier in tint and returned to its proper plane. The ciliary congestion lessened, and vision doubled in acuity.

At 10 A.M., on the eighteenth day after admission to the hospital, the patient complained of a severe attack

of pain in the eye. This, which the resident surgeon of the hospital relieved by the use of the artificial leech to the corresponding temple, became so excruciating, that I was sent for 5 hours later. Finding the gross signs of an acute attack of glaucoma with intraocular tension increased to plus 3, I immediately made a broad clean iridectomy down and in, in the position at which the iris tissue seemed to be the best adapted and most healthy. There was no accident, and no complications except the appearance of a slight hemorrhage from the iris into the anterior and posterior chambers. The tension of the eyeball at once fell to normal. On the following day the wound healed.

In a week's time, the blood in the chamber had disappeared, the eye was quiet and painless; and intraocular tension remained normal; but the colobomatous area was much smaller and fast becoming annihilated. New connective-tissue strands had appeared, and denser capsular thickenings had taken place, so reducing vision that the patient was unable to see more than light, though fortunately in a large, well-formed and uninterrupted field.

Fearing the occurrence of another attack of secondary glaucoma as soon as the communication between the two chambers had closed, I, 2 days later, made a broad iridectomy to the temporal side of the previous one. This done, I immediately, without the loss of any vitreous humor, extracted nearly the entire lens in a wire loop, removing all of the visible portions of the remaining lenticular matter with repeated flushings of warm sterile solutions of boric acid. After cleansing the field of operation, I, not fearing any glaucomatous exacerbation, instilled several drops of atropin, and carefully bandaged the organ. Iced compresses, directly applied on the dressings, were at once begun, and the patient was kept in bed.

The immediate results were more than I had expected. Both central and peripheral vision remained as before. The eye was quiet, intraocular tension was normal, and the new pupillary opening was fairly well preserved.

Feeling sure that with care no gross inflammatory reaction would arise, and that there was but a remote danger of another glaucomatous attack, I allowed the patient to return to his home for the summer months, enjoining him to continue the use of the atropin, not to attempt to employ the eye, and to return immediately to the hospital, should anything untowards occur.

In October, the patient, in accordance with promise, returned. The pupillary area having been lost from the low-grade irido-capsulitis, induced me first to endeavor to make a new one by the performance of Knapp's operation for irido-cystectomy.

This I did most successfully, obtaining a new pupil through both the iris and the underlying false membranes and thickened capsule. The opening, although irregularly shaped, was 3 by 4 mm. in size and was centrally placed.

The case was dressed and cared for in the same manner as before.

As a result, vision in a larger clear field again arose to what it had after the first iridectomy ($\frac{1}{3}$ of normal).

Again the patient was ordered atropin and permitted to return home.

On March 21, 1900, he reported once more. At this visit it was noticed that although the effects of the iridocystectomy had remained intact, yet a bulging capsular mass, apparently containing some dense material, was situated immediately behind the entire

pupillary area;—thus practically again reducing vision to light-perception.

The eye being unirritated and visual projection good, and not wishing to disturb the good results of the iridocystectomy, I had recourse to Tyrrell's method of drilling. Furnished with a good needle similar to that of Saunders, I followed the plan practised by Tyrrell with identical results; a few drops of translucent lens matter escaping into the anterior chamber through the broad opening made into the anterior capsule.

As an immediate result at the time of the operation, the patient was able with the aid of a convex spherical lens of ten diopters' power to see every motion given to a small lighted taper held some 10 meters' distance away. This rough test was most promising.

No reaction ensuing in one month's time and the patient having a corrected vision of one-third of normal ($\frac{5}{15}$), he was told to continue the use of the atropin and was allowed to wear a properly-chosen cataract lens.

At present writing, nearly one year since the completion of the series of radical procedures instituted for the restoration of the patient's vision, the conditions remain unchanged, the eye is quiet, the sight is still one third of normal, and the patient is daily employed in making his living as a laborer in the coal mines.

Remarks.—For a number of reasons the clinical history of the case is both interesting and important: The retention of the foreign body in the injured eye for 15 weeks' time—with the production of sympathetic disease before the enucleation of the offending organ; the marked increase of the gross symptoms of sympathetic iridocyclitis and iridocapsulitis one week after the removal of the primarily inflamed eye; the abeyance of the coarse signs of the inflammation by the employment of appropriate treatment; the continuance of the low grade inflammatory changes in the anterior segment of the organ; the occurrence of the attack of acute glaucoma, with its relief by a promptly performed uncomplicated iridectomy; the making of the second iridectomy and the successful removal of the bulk of the crystalline lens by means of a wire loop without the loss of any vitreous humor in order to prevent the recurrence of the glaucomatous condition; the persistence of the painless iridocyclitic and iridocapsulitic processes until, when seen for the second time, 6 months later, the pupillary area was lost; the restitution of the pupil by the performance of a Knapp's iridocystectomy; the preservation of the new pupillary area with the appearance of the underlying capsular and lenticular mass extending over the entire pupil space again reducing vision to the perception of light; and at last, the obtainance of a large permanent opening through the capsulolenticular mass by the drilling operation of Tyrrell giving the patient an acuity of vision of one third of normal:—all may be mentioned as worthy of citation.

The use of diphtheria serum in Italy, and other countries as well, is likely to receive a severe check, says the (London) Chemist and Druggist. The Serotherapeutic Institute of Milan made a batch of serum on November 24, into which the tetanus bacillus was accidentally introduced. The result has been that eight persons on whom the serum was used have met with horrible deaths from tetanus. The institute was instantly closed, the serum was destroyed, and an effort made to recall all supplies in the hands of dealers. The accident naturally caused a great scare in Italy.

A CASE OF UNILATERAL, PROGRESSIVE, ASCENDING PARALYSIS.¹

By WILLIAM G. SPILLER, M.D.,
of Philadelphia.

Professor of Diseases of the Nervous System in the Philadelphia Polyclinic;
Associate in the Wm. Pepper Clinical Laboratory,
University of Pennsylvania.

IN the April (1900) number of the *Journal of Nervous and Mental Disease*, Dr. C. K. Mills reported a case of unilateral, progressive, ascending paralysis, probably representing a new form of degenerative disease. His patient was a man, 52 years old, who, about 2 years before coming under observation, had been noticed to occasionally stub his right toes and scrape his right heel, and to give other evidences of slight weakness or awkwardness of the right lower extremity. The man was sure that the weakness in the right lower limb came on slowly. It was not until the implication of the right lower limb had been apparent 18 months that he noticed any weakness of the right upper limb. This weakness gradually became more perceptible, and a tendency to carry the limb against the body and flexed at the elbow was present. The weakness in the upper limb was much less than that in the lower, and some paresis of the face was detected. The right lower limb became wasted. A distinct Babinski reflex was not obtained, and no changes in the fundus were observed. I had an opportunity to examine this very interesting case. As the man was an intelligent physician his statements were reliable.

Unilateral, progressive, ascending paralysis is not a common symptom-complex, and yet a case very similar to the one reported by Dr. Mills has come under my care at the Polyclinic Hospital during the past year:

A peddler of Jewish parentage, from Austria, 41 years of age, who denies all venereal disease, began 4 years ago to feel weak in the left lower limb while walking. This weakness gradually became more intense, and in about a year his left upper limb began to get gradually weak. He is positive that about a year elapsed after the implication of the lower limb before he felt any weakness in the left upper limb. He was not unconscious at any time, and has never had vertigo, headache, vomiting, nausea, or convulsions. Diplopia has never been observed. At the present time the movements of the left lower limb are very spastic but not in the least ataxic, the toes of the left foot are scraped along the ground in walking and the left foot is turned inward. The movements of the right lower limb are not spastic. The patient states that he is obliged to have a new sole put on the inner side of the left shoe every 4 weeks, as he wears away the shoe by constantly scraping it along the ground. The right kneejerk is prompt, but the left kneejerk is much more so. Ankle-clonus has been obtained on the left side, but not on the right. Babinski's reflex is very distinct on the left side, but is uncertain on the right side. The resistance to passive movement in the left lower limb is below normal, but the spasticity seems to be even greater than the weakness. Sensation for pain, touch and temperature is normal everywhere over the body. The lower limbs are fairly well developed, the left thigh in about its central portion measures in circumference 39.5 cm., the right 40 cm. The reactions to the galvanic current are normal when the electrode is applied over the left external popliteal nerve or the muscles on the outer side of the left leg below the knee. Some rigidity on passive movement is felt in the left lower limb. The man stands well alone on either limb.

The resistance to passive movement and the grasp of the hand are distinctly less in the left upper limb than in the right. The tendon reflexes in the left upper limb are exaggerated. Von Bechterew's scapulohumeral reflex on the left side is also exaggerated, and at one time a clonus of the upper arm was obtained. The left upper limb is held slightly flexed at the elbow and against the body, but no

¹ Read before the Philadelphia Neurological Society, October 22, 1900.

contractures exist in any of the muscles of the body. The weakness of the left upper limb is much less than that of the left lower limb. No atrophy is found in any of the muscles. The man uses the right hand almost alone in undressing himself.

Speech is normal. The mouth cannot be drawn up as well on the left side as on the right, and slight flattening of the left side of the face is noticed. The tongue goes slightly to the left when protruded.

The man has never had any rectal or vesical disturbance except that he occasionally finds some difficulty in retaining the feces.

An examination of the patient's eyes was made by Dr. H. F. Hansell, May 19, 1900. His report is:

"We find in the right eye the media clear, fundus normal, myopia 3 D. In the left eye the media are clear, arteries small, veins normal, edges of disc distinct. The nerve head is white, the atrophy probably being spinal in origin, as there is no indication of a previous neuritis. Myopia 6 D. Reaction of pupil is normal."

This case, therefore, is very similar to the one reported by Dr. Mills, but the duration of the symptom-complex has been longer. The optic atrophy in the left eye, in association with the left-sided weakness and spasticity of the limbs, is a singular observation, the significance of which cannot be determined. A *slowly developing* paresis with marked spasticity of one lower limb, *extending after a year* to the upper limb of the same side, though in less intensity, and implicating very slightly the left side of the face; associated with exaggeration of all the tendon reflexes on the left side of the body and with a very distinct Babinski reflex, is a most striking symptom-complex. While the patient at present presents much the condition of one with ordinary hemiplegia, the history of the affection distinguishes it fully. He has never had anything resembling an apoplectic stroke. The heart is normal. The right side of the body is not implicated, except that the kneejerk on this side is very prompt. The greater implication of the lower limb is not common in hemiplegia resulting from a focal cerebral lesion.

The case can hardly be considered one of neuritis. The exaggeration of the reflexes, the unilaterality of the symptoms, the absence of sensory disturbances, etc., exclude neuritis.

An atypical form of disseminated sclerosis might be thought of, but this disease seems hardly probable. The usual symptoms of disseminated sclerosis are absent, and it would be an extraordinary grouping of the sclerotic foci which would leave the right side of the body intact and cause a gradually ascending and spastic paresis of the left side, very pronounced in the lower limb, less so in the upper, and still less so in the face.

Within a period of 4 years some more distinct symptoms of disseminating sclerosis would be expected.

Hysteria hardly seems probable on account of the absence of hysterical stigmata, the presence of the Babinski reflex, the left optic atrophy, etc.

The case might be thought to be one of unilateral amyotrophic lateral sclerosis. Probst, in his paper in which he has collected a large number of cases of this disease, states that in 9 amyotrophic lateral sclerosis began in a hemiplegic form. I have examined these abstracts as given by Probst, and when the cases seemed to have any relation to mine I have studied the original papers. None of these cases correspond with those of gradually ascending unilateral paralysis reported by Dr. Mills and myself. The one that has the greatest resemblance is reported by Vierordt. A man, 48 years old, began in August, 1878, to have weakness of the right lower limb, and in the early part of 1879 weakness

of the right upper limb; then atrophy of the thenar and interosseous muscles of the right hand developed. In 1880 weakness and atrophy were observed in the left upper and lower limbs. The disease therefore extended within a few months from the lower limb to the upper on the right side, and within two years the left extremities were implicated. Amyotrophic lateral sclerosis, even when in rare cases it begins in a hemiplegic form, has a much more rapid course than the progressive ascending unilateral paralysis as seen in Dr. Mills' case and mine, and atrophy, which was absent in my case after four years' duration of the disease, begins early. Optic atrophy, however, has been observed in amyotrophic lateral sclerosis (Lannois and Lépine).

The possibility of a cerebral lesion implicating first the center or the nerve fibers for the lower limb, and later those for the upper limb and face must be considered. A hemorrhage could hardly produce the symptom-complex, although thrombosis might. We should expect more symptoms after a period of four years if the cause were tumor or abscess, and in my case all distinct symptoms of intracranial disease were absent. The man never had nausea, vomiting, headache, vertigo, convulsions, optic neuritis, or mental disturbance, and optic atrophy which he did have on one side is not necessarily a sign of cerebral disease. We cannot, however, exclude the possibility of some intracranial lesion as the cause of the symptoms.

Dr. Mills believed that a gradual degeneration of one pyramidal tract would best explain the symptoms in his case. The symptom-complex caused by primary degeneration of the central motor tracts consists of gradually developing paresis and rigidity, especially in the muscles of the lower limbs, spastic paretic gait, exaggeration of the tendon reflexes, integrity of sensation, absence of marked muscular atrophy, absence of disturbance of rectum or bladder, absence of vasomotor or trophic signs and of mental symptoms. The course of the disease is chronic and the affection is often stationary for years. Death is usually from an intercurrent disease.

The cases of lateral sclerosis with necropsy are exceedingly rare. I can refer to those of Dreschfeld, Dejerine and Sottas, Friedmann, Ida Democh, and Meyer, and yet not one of these five cases was entirely uncomplicated. In Dreschfeld's case some of the cells of the anterior horns were diseased; in Dejerine and Sottas' case the columns of Goll were not perfectly intact in the cervical region; in Democh's case symptoms of neuritis were present, and in Friedmann's case and Meyer's the direct cerebellar tract was not normal. These cases seem to show, however, that isolated primary degeneration of the pyramidal tracts is possible, but that a sharp distinction between such a form of degeneration and combined systemic disease is difficult or impossible.

The case reported by Dr. Mills and the one by me have the symptoms one should expect from unilateral lateral sclerosis, but we can hardly dare to hope that the pathology of the affection will speedily be determined, inasmuch as it has taken about 25 years to establish the possibility of primary bilateral degeneration of the pyramidal tract. The symptoms in our cases could best be explained as the result of unilateral degeneration of the pyramidal tract, but we are cautious in saying that this is the condition present.

Dreschfeld at first reported that the nerve cell-bodies of the anterior horns were normal, but he is said to have modified this statement later.

The recognition of a disease or a symptom-complex is usually first made from its clinical features, and the pathology of the affection is determined later. The reports of clinical cases of ascending progressive unilateral paralysis are, therefore, desirable. We have yet to learn the pathology of many well-recognized diseases. Obersteiner said at the recent Congress in Paris that when he began his medical studies few organic nervous diseases were known. Little was known of the pathology of tabes or disseminated sclerosis, and still less of syringomyelia.

CAVITE FEVER.

By B. L. WRIGHT, M.D.,

Assistant Surgeon, U. S. Navy.

AMONG the unclassified and unnamed fevers which were found to exist in the Philippines, upon the American occupation of these islands, was one with which the medical officers of the navy, attached to the Cavite Naval Station, came in immediate, constant, and close relationship.

The disease is constantly in evidence, usually in epidemic form.

Almost invariably every fresh arrival at the station contracts the disease within the first 2 or 3 weeks after taking up quarters on the peninsula.

At different times during the last year and a half 4 battalions of marines, consisting of from 300 to 400 men and officers each, in addition to numerous naval officers and bluejackets, have been quartered at the naval station, or within the limits of the Cavite peninsula.

Fully 70% of them have had the disease one or more times.

Those who leave the station, and, after a short absence return, are just as prone to become victims of the disease as are fresh arrivals from the United States or other parts of the Philippine group.

As far as I have been able to ascertain this fever is endemic, and principally confined to the immediate vicinity of the peninsula of Cavite; a strip of land not more than $4\frac{1}{2}$ miles long by $1\frac{1}{2}$ miles wide.

Sporadic cases of the disease are seen in other parts of the islands, but not often. Early in July, 1900, the U. S. S. *Manila*, then on her way to Sandakan, British North Borneo, had an epidemic of what I believe to have been this disease, break out, which temporarily incapacitated fully three-quarters of her crew, and all but one or two of her officers.

The disease is unknown in Borneo, and it was evidently contracted in Cavite, the *Manila* having left the navy yard at that place some 7 or 8 days prior to the outbreak.

Naturally the disease has been carefully studied by those officers of the medical corps of the navy who have been on duty at the station, and they have gradually separated it from other existing fevers, and by common usage it has become known as "Cavite fever,"* under

which title I have the honor of presenting it in this paper.

Cavite fever is an acute infectious disease, characterized by an abrupt onset, high temperature, severe muscular pain, and extremely tender and painful eyeballs. The predisposing causes are high temperatures, low, damp localities, overcrowding, and possibly the close proximity of salt water. The exciting cause is supposed to be, and undoubtedly is, microorganismal, although as yet nothing is known of its nature. Of the pathology we know nothing, as deaths from this disease have not been observed. The period of incubation is from 2 days to 2 weeks. The disease is of sudden onset, usually commencing with a slight chill; in a few hours the temperature rises to a 104° or 105° and may even reach 107° .

The face is flushed, the eyes injected, extremely painful and tender; the skin burning hot; the pulse full, strong and rapid; the respiration accelerated, and the mind frequently delirious; the patient extremely prostrated.

Nausea and vomiting are usually present, the bowels constipated, and the urine scanty and high colored. Headache and muscular pain are severe; the latter usually located in the muscles of the back and legs, but occasionally in those of the arms and shoulders. The temperature usually continues high, for from 3 to 5 days, when it falls by crisis; the muscular pain may or may not cease with the fall of temperature.

Relapses are not common, but second, third, and even more attacks are not unusual.

This disease is most apt to be confounded with dengue, but the absence of an afebrile period, and the rash, followed by a second febrile attack of definite duration, enables one to distinguish it from that disease. The absence of catarrhal symptoms separates it from catarrhus epidemicus.

The treatment should be as follows: Rest in bed, with a liquid diet. The bowels should be freely opened by a brisk saline purge, and kept regular by small and frequently repeated doses of calomel. Such drugs as antipyrin, phenacetin, or acetanilid, and small doses of quinin should be administered.

A good combination, which also includes the proper amount of calomel, is as follows:

R.—Antipyrin 3.8 grams.
 Quinini sulph. 1.2 grams.
 Hydrarg. chlor. mit. 0.1 grams.

M. ft. Cap. No. XII. Sig.—One capsule every 2 or 3 hours.

The high temperature should be controlled by sponge baths, or by "tubbing," and an ice-cap should be applied to the head. For a week or 10 days after recovery, tonics, such as iron, quinin and strychnia, should be given.

I am strongly of the belief that the muscular pain is due to a toxic peripheral neuritis.

Several cases of this condition, with foot-drop and muscular atrophy, occurred on the station, which at the time were ascribed to other causes, but which I am now inclined to believe were the toxic effects of a former attack of Cavite fever.

A case of complete atrophy of the right supraspinatus, infraspinatus, teres major and minor, and the trapezius, associated with dislocation of the right scapula, and drooping of the shoulder, occurred in the case of one of the officers of the U. S. S. *Manila*, and when seen last, just before he left for the United States, the left shoulder and arm were becoming affected.

* So named by Surgeon George Pickereil, U. S. Navy, Surgeon of the Yard and Station. He was one of the first to study the disease and to classify its symptoms.

EXOPHTHALMIC GOITER OF SYPHILITIC ORIGIN.¹

By R. ABRAHAMS, M.D.,
of New York.

District Physician to the Mt. Sinai Hospital; Physician to the Surgical, Skin and Venereal Departments, East Side Dispensary, New York.

IN presenting this communication, I am not unaware of its inadequacy. The clinical data therein contained are not sufficient to engage the attention of my fellow practitioners. But the truth remains, now as ever, that the bedside is mightier than the laboratory; and that one carefully observed *clinical* fact is more useful to the patient and his medical attendant than a thousand slides and sections.

The three cases, to be presently described, carry with them a strong hint at the etiology and treatment of a very obscure and obstinate disease. And as he who runs may read, so he who doubts may try.

CASE 1.—Mrs. C. H., 35 years old, mother of three children. Her family history is good. Her personal history was good until the spring of 1894. At that time she contracted syphilis from her husband. The initial lesion was a large ulcer situated on the right labium majus. In due time the secondary symptoms appeared in the form of small and large papules. The eruption was severe and universal. At this stage she came under treatment. I may add that the mouth, tonsils and pharynx contained many mucous patches.

This woman was put on daily mercurial inunctions, 5 grams per dose. After receiving 50 rubbings of the ointment all the luetic manifestations disappeared, and the patient, though not the doctor, believed herself cured, perfectly and forever.

Five months later, the same victim visited the office with new patches in her mouth. On this occasion she also presented an enlarged thyroid gland and protruding eyes. Her story was that "the swelling of the neck and the bulging of the eyes came on simultaneously two months ago." Coincidentally with this she grew short of breath and experienced a distressing palpitation of the heart, which, according to her statement and language, "made her very nervous."

Mere inspection of the patient was enough to establish the diagnosis of exophthalmic goiter. The three cardinal symptoms of the disease were present to an extent to enable a tyro to interpret their meaning. The staring, bulging eyes; the enlarged, soft and pulsating thyroid, and the rapid heart action (from 110 to 120 per minute) were in evidence to a convincing degree. Anemia and tremor of the hands were quite marked; Grafe's and other minor signs were absent.

While the mucous patches were treated locally with silver, her other trouble was combated with the regulation medicines, namely: strophanthus, digitalis, ergotin, arsenic, and iron, producing absolutely no effect on the morbid condition of Basedow's. At the lapse of 8 weeks of trial and trouble, the woman began to complain of excruciating headaches, occurring especially in the night. This additional misery necessitated the administration of an iodid. The saturated solution of iodid of sodium was chosen, to be taken in gradually increasing doses. Beginning with 15 drops the patient reached the dose of 2 drams within 12 days. The relief from her headaches was established in a few days. Hand in hand with this, signs of improvement in her other morbid phenomena were appreciably noticeable. The pulse slowed; the goiter diminished and the eyes visibly receded. The drug was continued, after the headaches had gone, with short intermissions, for a period of 2 months when the exophthalmic goiter with its retinue of symptoms vanished. The woman had no return of the ailment ever since.

This case made a deep impression on me and naturally set speculation agog. Here is a woman in whom the syphilitic process is still smouldering, as evidenced by the appearance of patches in the mouth and head-

aches in the night. Now this woman develops a typical form of Grave's disease. Then, upon the energetic exhibition of one of the old therapeutic stand-bys of lues, the disease melts away as if it were a gumma or a specific periostitis. The conviction forced itself on me, as it would, I have no doubt on many another, that the exophthalmic goiter in this patient was caused by syphilis and cured by remedies antagonistic to syphilis.

Still, as one swallow makes no summer, so one case makes no conclusive evidence. And so the written notes and the mental comments lay smouldering until the generous "law of multiplicity" threw another case into the crucible of experience, namely:

CASE 2.—Mrs. Y. K., 36 years old, married, mother of 5 healthy children. Family history good. Personal history: In 1894, shortly after the birth of her last child, she had a sore on her vulva, followed by enlarged inguinal glands. A few weeks later, she says, "blotches" appeared on her body and forehead. Her throat troubled her and the hair of the head was rapidly falling out. These symptoms and conditions she distinctly remembered. Instead of consulting a physician she chose to be treated by a friend, a man who served as orderly in a "European Hospital." The treatment apparently satisfied the patient as she made no effort to see or be treated by a medical man. In 1896, two years after her initial trouble, her history and status were briefly as follows: Three unprovoked abortions, a flattened nose due to destruction of the septum and a large perforation of the hard palate. There was a goiter of considerable size; mildly protruding eyes, and a heart action of 90 to 100 to the minute. These latter slowly came on during 1895. In every other respect the patient was well. The woman's main desire was to get rid of the "swelling of the neck which disfigured her."

Treatment.—Daily inunctions for 6 weeks; result: complete disappearance of the exophthalmic goiter and no recurrence of it since then.

Now, in analyzing this case, the following facts and conclusions are preeminent: The patient's own story, though not couched in learned words, is strongly suggestive of an attack of syphilis of no remote period. The sore on the genitalia; the enlarged inguinal glands; the "blotches" which might correspond to a roseola or papular syphilide; a sore throat which might have been mucous patches; and, lastly, a falling of the hair, which needs no comment or explanation. This strong suspicion of syphilis becomes incontrovertible evidence of it, when the patient appears for treatment 2 years later—the three spontaneous abortions, the deformity of the nose and the destruction of the hard palate, all of which developed since the occurrence of the genital sore and the cutaneous "blotches." With this history and this anatomical evidence before me, there was no escape from the lurking suspicion that the patient's syphilis might be the parent of her exophthalmic goiter. The proof afforded by the result of the treatment supplies overwhelming evidence in favor of the belief that this case of Basedow's disease was unquestionably of syphilitic origin.

In anticipation of a natural question which may be asked regarding the different specific remedies which were employed in the two cases, to wit., iodid of sodium in the first and mercury in the second. The answer is this: The first woman having been under my care almost from the very inception of her affliction has received a proper and methodical mercurial treatment. And when she returned a few months later complaining of syphilitic headaches the iodid was given, and with marked benefit all around, including the exophthalmic goiter. In the second woman, however, the assumption

¹ Read before the New York State Medical Association (New York County), January 21, 1901.

was that her medical attendant, the orderly, did not and could not put her on mercury, enough, at least, to do her good, and so she was given the benefit of inunctions with the stated satisfactory result.

CASE 3—Sadie K., a woman 27 years old, single. She does not know much about her family. Father and mother died from causes unknown to her. Her history is as follows: At the age of 20 she adopted an immoral life. In a short time gonorrhea knocked at her door, and she had scarcely finished entertaining this visitor when a hard chancre availed itself of her hospitality. In 1897, when she considered herself cured and in good health, she began to have palpitation of the heart. This kept up for about 3 months, when the thyroid gland began to enlarge. Her eyes were always well and showed nothing abnormal at this examination. For a year she was treated by private and dispensary physicians with no result. In 1898 she came under my treatment. She then presented a typical goiter, and a pulse ranging from 110 to 130, very nervous and very despondent. The story of her syphilis was so plain and perfect that it could not have been told better by an amateur specialist. The only physical sign that could be found to corroborate her history of infection, however, was a very slight leucoderma on one side of her neck.

As this case appeared to be in line with the two preceding ones, the patient was accordingly put on iodid of sodium, saturated solution, until she took 3 drams a day. The good effects of the immense doses of the drug began to show in less than a month. The heart-action was wonderfully improved and the diminution in the size of the goiter was appreciable from week to week. In 10 weeks, during which time the treatment was suspended for a few days, the whole pathological condition was obliterated. Tonics and improved nourishment restored the woman to perfect health.

An attempt was made to administer mercury by injection and inunction, but the patient had an unconquerable repugnance to mercury in any shape, form or manner, even when it was ordered as hydrargirum.

This is the sum total of my successful experience with exophthalmic goiter. The line of treatment in each and all of the three cases proceeded from a clear and definite conception of the etiological factor, which was presumptively, if not positively, responsible for producing the disease.

In reviewing the clinical memoranda which are presented in this paper, a few running comments and conclusions are, perhaps, justifiable:

1. The occurrence of exophthalmic goiter in three undoubted syphilitics cannot be regarded as either an accident or coincident.
2. The old dictum which relegates the origin of exophthalmic goiter to a perturbation or disturbance in the cervical sympathetic system should receive attention only after the existence of syphilis, present or past, be absolutely excluded.
3. Those cases which yield to mercury or iodids should be favorably looked upon as being of syphilitic origin.
4. Cases in which all the orthodox remedies fail should be put to the test of specific treatment.
5. Cases which are characterized by gangrene of the extremities, various pigmentation of the skin, nocturnal headaches, or other suspicious luetic symptoms, should receive the benefit of specific remedies.

In conclusion, I must plead ignorance of any literature bearing on the relation of Grave's disease to syphilis. Should such exist, I shall then find consolation in the wise man's saying that "there is nothing new

under the sun." On the other hand, should I be treading on virgin soil, I leave it to you to cultivate it, so that in the near or distant future a better and larger harvest can be gathered and reported by the tillers and toilers of our exalted science.

THE SURGICAL IMPORTANCE OF APPARENTLY SIMPLE CARBUNCLES AND FURUNCLES OF THE UPPER LIP.

By CHARLES A. POWERS, M.D.,

of Denver, Col.

IN 1886 or 1887, a young physician, attached to the out-patient department of the Chambers Street Hospital, complained one day of a small boil on his upper lip. This was moderately tender and painful. He said that he felt generally indisposed and thought that he would stop work for a day or two. Two days later we were greatly surprised and grieved to learn that he was dead with all of the symptoms of acute pyemia and septic meningitis.

During the winter of 1890-1, Dr. B. E. Vaughan brought to me a young gentleman, a student in the College of Physicians and Surgeons, who was suffering with a moderate-sized carbuncle on the left side of the upper lip, just below and without the ala of the nose. The swelling was hard, brawny, indurated, and tender, the entire right side of the lip was considerably swollen, the swelling extending well up on the cheek alongside of the nose to the margin of the orbit. This cheek swelling was also brawny and indurated. The young man felt quite ill; his pulse was 110, his temperature 102°. He had severe headache. He was at once sent to the New York Cancer Hospital, now known as the General Memorial Hospital, where I speedily operated under ether. Incision into the carbuncle revealed no free pus, but the ordinary necrotic area which we see in carbuncles, occurring, let us say, at the back of the neck. This necrotic area was fairly wide, extending over an area $\frac{1}{2}$ of an inch in diameter, its depth going to the mucous membrane of the lip. It was found to be continuous with another necrotic area at the seat of a brawny cheek induration, and the incision was carried outward and upward into this. The entire necrotic area was thoroughly excised, the incision extending necessarily well up toward the margin of the orbit. The wound was packed and an ordinary dressing applied. The temperature and pulse promptly fell, and in 3 or 4 days the young man felt entirely well. The wound healed from the bottom, leaving a rather ugly scar.

On the morning of August 11 of this year Dr. S. G. Bonney kindly asked me to see a young gentleman of 17 years who had a furuncle of the upper lip of about 24 hours' standing. This furuncle was of moderate size, perhaps half as large as half a cherry, brawny, indurated, tender, and painful. The entire lip, more especially its left side, was greatly swollen, and this swelling extended to the left cheek. The cheek was not indurated. The young man felt rather ill; his temperature was 101, his pulse about 100°. The nature of the swelling was explained to his parents. They were told of the danger of septic thrombosis of the facial veins, this extending to the cerebral sinuses and causing a rapid and fatal pyemia. They readily assented to operation, and 2 hours later the young man was etherized at St. Joseph's Hospital, and the necrotic area of the furuncle thoroughly excised through the smallest possible incision. The wound was packed and left to heal from the bottom. The symptoms promptly subsided. At the end of 24 hours the young gentleman was removed to his home, and 2 days later he was out and about. The resulting scar is small, and so placed that it will in due time be concealed by a moustache.

Dr. Bonney, who first saw this patient, said: "I remember that many years ago, while a student at the Harvard Medical School, I was impressed by a statement made by Professor Cheever in his lectures on sur-

gery. He said: 'One of these days it may happen to some of you to see a rapidly forming, brawny carbuncle of the upper lip. Remember that these are fraught with extreme danger. The septic process rapidly occasions a thrombosis of the facial veins, this leading to a speedy pyemia and death.'

On August 30 of this year a young man of 22 entered my office suffering with a furuncle of the upper lip, much like that just described, except that the brawny area was located somewhat near the angle of the nose and was beginning to extend upward on the cheek. It was of about 48 hours' duration. It had been exceedingly painful, the young man felt quite ill. His temperature was 100°, his pulse 104. The patient was at once removed to St. Luke's Hospital, where the necrotic area was excised under ether. The main area in the lip proper was about $\frac{5}{8}$ of an inch in diameter, extending well down to the mucous membrane. This was continuous with a necrotic area on the cheek just outside and above the ala nasi, this last area being about half the size of that in the lip. Through the smallest possible incision the entire mass of necrosed tissue was removed. Dr. W. C. Mitchell, professor of bacteriology in the University of Denver, was present and took cultures. The growth showed a pure culture of the *Staphylococcus pyogenes aureus*. The outer and upper angle of the skin-incision was sutured, the rest of the wound packed with iodoform gauze and the usual dressing put on. Twenty four hours later the pulse and temperature were normal; prompt recovery followed.

The foregoing cases are typical of a condition which is fraught with great danger and the importance of which is perhaps insufficiently appreciated by many practitioners of medicine. Unless these carbuncles or furuncles are promptly and thoroughly excised, rapid thrombosis of the facial veins, extending to the cerebral sinuses, is apt to ensue and a speedy and fatal pyemia supervenes. Excision had best be done under general anesthesia, and the earlier it is performed the smaller will be the necessary incision with its resulting scar. It is seen from the foregoing cases that even a moderate delay may necessitate the excision of a large necrotic area from the cheek. In certain cases it may be possible to do the operation through the mucous surface of the lip. This incision is especially useful in women. The danger in all these cases is not from the bacteriological form of the infection but from its location.

A CASE OF COCAIN HABIT OF TEN MONTHS' DURATION TREATED BY COMPLETE AND IMMEDIATE WITHDRAWAL OF THE DRUG.

By GEORGE WILLIAM NORRIS, A.B., M.D.,

of Philadelphia.

R. C. B., a dentist by profession, aged 30, presented himself at the Pennsylvania Hospital as a voluntary patient in December last, and came under the care of Dr. A. V. Meigs with the following history:

Ten months previous to his admission he had suffered severely from hemorrhoids, for the relief of which he had used cocain locally by rectal injection. On cessation of pain he still continued to use the drug in daily increasing doses [now per hypodermic injection] on account of its stimulating and exhilarating effect; and when first seen at the hospital had been taking on an average 16 grains per diem.

He stated that until within a week he had daily attended to his practice; doing, he thought, as good work as at any time, but accomplishing less in the course of 24 hours, and feeling a constant tendency to procrastinate. Time to him passed very rapidly; minutes seemed like seconds, and he experienced a continual, voracious, insatiable appetite. When taking alcohol, to which he had at one time been addicted, he found that it counteracted the effects of the cocain; larger doses of this drug being required to produce

the usual effect. Insomnia was constant unless he took cocain; upon the injection of which in small doses he slept well for one or two hours, when its repetition was necessitated. Single large doses kept him awake. For several months he had been troubled with hallucinations of hearing, and while semiconscious of his true condition, had avoided street cars and public gatherings where he imagined voices accused him of being a "cocain fiend," etc. At night he would wander from room to room in his efforts to escape the voices which he heard talking about him, calling out, "Look, he's going to take another;" and while reasoning with himself on the subjective character of his troubles, yet was impelled by their vividness to flee from them as from real existences.

During the week previous to his admission he had had syncopal attacks, whenever injections were omitted for more than two hours, and, as he said, he had been very "excitable," having broken several hypodermic needles in his muscles. About this time he became alarmed at his symptoms and sought aid at the hospital.

Physical Examination.—A prematurely gray, lean, pale individual, with marked mydriasis, a slight tremor of the hands and tongue, restless, furtive glances, excited speech and indistinct articulation. Temperature, 97; respiration, 20; pulse, 88. The skin of his arms and legs shows innumerable hypodermic punctures. The first sound at the apex—sharp, short and high pitched. No murmurs. The other organs, as well as the urine, negative.

Treatment.—Complete withdrawal of cocain. Strychnin sulfate, $\frac{1}{16}$ gr., every fourth hour. Sulfonal, 20 gr., repeated in two hours.

On the first night the patient slept fairly well; on the second he required no hypnotic whatever; and except for the relief of an obstinate constipation needed no more active medication than the strychnin. He volunteered the information that he felt like his former self for the first time for many months, and that time once more seemed real to him. He complained of no craving for the drug and was allowed to leave the hospital a week after his admission [having pleaded financial obligations] on promising to place himself under medical surveillance.

The interesting features of the case are: 1. That sudden and entire withdrawal of the cocain after long-continued use in large doses required no more active therapeutic substitution without producing physical effects. 2. That the patient after the first 12 hours seemed to experience so little craving for the stimulant but remained contentedly in bed, reading the newspapers, and suffering none of the agonies usually experienced on the discontinuance of a long-established drug habit.

On looking over a considerable number of reported cases of acute and chronic cocain intoxication, the following facts have been gleaned which it may be of interest to tabulate:

1. Cocainism is the most insidious of all drug habits. The use of the drug being unaccompanied by disagreeable after-effects—headache, nausea, vomiting, etc., which are met with after the ingestion of opium or alcohol—the vice is readily and rapidly established.

2. Cocainism is occasionally acquired by the local use of the drug in diseases of the nose and throat, teeth, etc., but more often as a substitute for opium or alcohol.

3. Cocain is eventually tolerated by the system in huge doses. (One case is recorded where 60 grains were daily consumed.)

4. A relatively large number of habitues are found in the medical and dental professions. (It is said 30%.)

5. The continued indulgence in cocain invariably, and usually soon, leads to marasmus, with mental, moral, and nervous degeneration.

6. The smallest fatal dose on record is $\frac{1}{2}$ grain hypodermically.⁵

7. While many cases of acute intoxication are being continually reported, there are relatively few fatal cases. The majority of such are the result of large doses injected into the urethra and bladder, *e. g.* :

5 fluidrams of a 5% solution into urethra.¹

6 fluidrams of a 5% solution into urethra.²

8. The amount of cocain sold yearly is rapidly increasing, and its self-prescribed use among the laity and lower classes becoming proportionately more frequent.

REPORT OF A CASE OF ENORMOUS VENTRAL HERNIA; OF A CASE OF DERMOID CYST OF THE OVARY; AND OF A CASE OF PROFOUND SHOCK FOLLOWING A CRUSH OF THE ARM.¹

By FRANCIS T. STEWART, M.D.,

Out-Patient Surgeon to Pennsylvania Hospital; Associate in Surgery, Philadelphia Polyclinic.

I AM indebted to Dr. Martin for the privilege of operating upon and reporting the following cases:

CASE 1.—A. C., aged 40 years, was subjected to abdominal section four years ago for pelvic trouble, the nature of which is unascertainable. She remained in the hospital one year and was kept supine several months. A small hernia was noticed two months after operation; this rapidly increased in size as she began to walk about. The patient is thin but apparently strong. The bowels are always sluggish and often obstinately constipated, but there are no evidences of interference with the other abdominal organs. The heart, lungs, and urine are normal. When the patient is standing, a large, soft, tympanitic tumor projects from the abdomen and hangs down below the pubes. When she is lying down, the protuberance disappears, and after persistent efforts at reduction a mass the size of two fists still remains. The ring formed by the separation of the recti extends vertically for 7 inches and laterally 4 inches. Two surgeons had seen the case and refused to operate.

She entered the Pennsylvania Hospital December 19, 1899, was put in bed and given mild aperients for 10 days without any material diminution of the hernia. Under ether an incision was made from just below the ensiform process down nearly to the pubes; the thickened sac was immediately encountered and opened; it contained the lower half of the stomach, all of the transverse colon, and most of the small intestines including omentum and mesentery. Adhesions were numerous and dense. Owing to the diminished space within the peritoneal cavity almost all the omentum was excised with the sac. The intestines, "having sacrificed their right of domicile in the abdomen," were most difficult to replace; they were attacked, with the patient in the Trendelenburg posture, with a great deal of force, a large amount of coaxing, and were finally induced to return to the abdominal cavity. The peritoneum was closed with a continuous catgut suture; each rectus was loosened from its sheath, slid inwards, and united to its fellow by heavy chromicized catgut (I should use silver wire in a future case), and the skin was sutured with silkworm-gut. Broad adhesive strips were applied to support and strengthen the belly wall. The operation consumed 1½ hours. There were considerable shock and much vomiting. The respirations registered 60 to the minute, remained rapid for one week, and were out of all proportion to the pulse-rate. The patient was kept in bed one month. After two months there was no recurrence.

In most cases of very large hernia, operation is said to be unjustifiable because of the difficulty and often

impossibility of accomplishing reduction, on account of the increased danger to life, and for the reason that it is usually fruitless, the rupture reappearing and rapidly attaining a large size. We attempted operation in the case under consideration because of the increasing intestinal interference and unmanageableness of the tumor, believing that we at least could make the opening small enough to be covered by a truss, and in order to gratify the patient, who appreciated the peril and the uncertainty of cure, but who was willing to hazard any procedure essayed to mitigate her distressing condition.

CASE 2.—A. B., aged 33 years, was admitted to the Pennsylvania Hospital January 29, 1900. She had had one child, 1½ years before. The menses had been absent 6 weeks, during which time she complained of pelvic pain and leukorrhea. Bimanually an adherent mass could be felt behind the uterus on the right side. A diagnosis of ectopic gestation was made. At the operation the mass proved to be an inflamed dermoid cyst of the ovary, containing fatty detritus, cholesterine, compound granular cells, pus cells, and two perfectly formed but atypical teeth. The recovery was uneventful.

Formerly cases of this character were regarded as imperfect ovarian pregnancies with or without sexual intercourse; the ovary was thought to be autogenetic; and the absence of menstruation, which sometimes precedes the discovery of the cyst, lends credence to this view, which still has its advocates. The fact that the ovary alone is selected as the seat of dermoids in preference to all the other abdominal organs, makes the inclusion theory equally difficult to comprehend.

CASE 3.—N. T., male, aged 23 years, was brought to the Pennsylvania Hospital October 14, 1900, by the patrol wagon. He had been found lying under a freight train with a badly mutilated left arm. He was cold, unconscious, wet with rain, and covered with dirt and cinders. The pulse could scarcely be felt, the respirations were shallow, the pupils dilated, and the axillary temperature approximately 88° F. The thermometer would not register, its lowest marking being 90°. With heat and stimulants the temperature reached 100° during the course of 10 hours. The arm was then amputated just below the shoulder joint. It was remarked that the axillary vein contained a thrombus extending far above the point of ligation. The patient reacted from operation and seemed to be doing very well, when he suddenly and unexpectedly expired, 5 hours after operation, from, as we believe, a large embolus blocking the pulmonary artery. There was no autopsy.

THE TREATMENT OF POSTOPERATIVE HERNIA.*

By IRVING S. HAYNES, PH.D., M.D.,

of New York.

Professor of Practical Anatomy, Cornell University Medical College; Visiting Surgeon to the Harlem Hospital; Member of the New York Academy of Medicine, of the Society of the Alumni of Bellevue Hospital, etc., etc.

THE cure of postoperative hernias is only by operation. These herniae are formed at the site of some previous abdominal operation. They are developed in the scar which gradually yields to the intra-abdominal pressure. The sac is formed of thinned skin and peritoneum united by attenuated scar-tissue. The omentum is usually united to the cicatrix and behaves often as in a typical umbilical hernia. The hernial ring is formed by the edges of the muscular and fascial layers of the abdominal wall welded into a compact whole by

¹ Read at a meeting of the Philadelphia County Medical Society, December 26, 1900.

* Read, February 7, 1900, before the Society of the Alumni of Bellevue Hospital.

scar-tissue. Strangulation does not appear often and if present is usually caused by a constricting band.

These ruptures are usually easily and completely reducible as regards the intestines, but, as just stated, in the majority of cases the omentum will be found adherent to the bottom of the sac. The following cases will illustrate the various conditions found in this class of hernia and the steps of the operation for their cure.

CASE 1.—Charles C., age 20, admitted to the Harlem Hospital October 16, 1895. Patient had been operated upon about one year previously for an inguinal hernia by O'Hara's method. A truss was worn after the operation. Seven weeks previous to admission to the hospital he left off the truss and the hernia reappeared while lifting. Examination shows a left inguinal hernia, reducible, but causing him great pain and interfering with his health. October 20 a Bassini operation was performed, after excising all the surrounding scar tissue. The internal inguinal ring was large, a large piece of omentum lay in the sac which reached to the scrotum. There were many old adhesions present. The omentum and sac were removed. Silk was used as a ligature for the sac and to close up the various muscular layers. The skin was united with the same material. The wound was slow to heal. Two or three sutures had to be removed to give vent to a bloody discharge. It finally closed, with the exception of a small sinus that discharged a few drops of pus daily. At his own request he was discharged December 16, 1895. Later he entered the Post-Graduate Hospital in the service of my friend, Dr. De Garmo. The doctor wrote me that nothing operative was done, that after a while two or three silk sutures were discharged and the sinus closed quickly. He was discharged with a firm scar and no return of the hernia.

CASE 2.—Alvin E., age 25, admitted to the Harlem Hospital January 4, 1896. November 8, 1895, was operated upon in Buffalo for septic peritonitis due to a perforated appendix. The wound was drained for nine days and then allowed to heal by granulation. Examination shows a scar 5 inches long, parallel with and just above Poupart's ligament; the center of the scar is over the middle and outer thirds of the ligament. The gut comes out through an opening just to the outside of the normal internal inguinal ring, and runs down under the skin along the front of Poupart's ligament into the scrotum, presenting many appearances similar to an indirect inguinal hernia. The hernia is easily and completely reducible. Operation, January 7. Incisions were made in normal tissues alongside the scar, exposing in turn all the muscular layers, a well formed hernial sac was present which was treated as in an inguinal hernia, being dissected free, ligated as high up as possible, and removed. The wound was closed as in a Bassini operation for radical cure of an inguinal hernia. The cord was placed in the outer angle of the incision, the transversalis and internal oblique muscles sutured firmly behind it to the inguinal ligament and the external oblique closed over the cord down to the external ring. Silk was the suture material, applied interruptedly in the two inner muscles, and continuously in the external one. The skin was closed with silkworm-gut and the wound sealed with aristo-collodion. Result: primary union. Patient discharged January 22, 15 days after operation. Union firm. He was seen February 23, when he was at work in a printing office lifting plates that weighed 60 pounds each. During the day he lifted and carried 240 of these plates, or 14,400 pounds. May 1, result remains absolutely perfect.

CASE 3.—Julia R. was operated upon at the Harlem Hospital by the writer September 21, 1896, for a general septic peritonitis due to a gangrenous and ruptured appendix. The peritoneal cavity required free drainage. The peritoneum, muscles, and skin were sutured with silkworm gut in a single layer, as haste was imperative. The child recovered and was discharged in a month, with a sinus present, which closed in December. The scar was a weak one and a hernia developed as large as a hen's egg. The covering of the hernia was very thin. The margins of the muscles could be plainly felt as a thick ring about the hernia. She was readmitted to the hospital and operated upon January 6, 1897. Incisions were made on each side of the scar and the cicatrix removed. The cicatrix included the skin and

peritoneum. The muscular margins were welded together by the cicatricial tissue. The cecum was adherent to the peritoneum along the inner margin of the scar. The peritoneum was dissected free about the margins of the wound and sutured. The adhesions of the cecum were not disturbed. The muscles were then separated and sutured separately by chromic gut applied continuously. Silkworm-gut was used for the skin and the wound sealed with collodion. Result: primary union. The child was discharged January 20, 16 days, with a firm line of union. Examined 6 months later the scar was solid. Both sides of the abdomen appeared just alike.

CASE 4.—Emma L., age 28, admitted to the Harlem Hospital January 12, 1897. Three months previous a median laparotomy had been performed in one of the city hospitals. A hernia in the scar soon developed. Operated on January 18, 1897. The ventral scar, 5 inches long, with the omentum adherent to the peritoneum was excised. The hernial sac was composed of omentum, peritoneum, superficial fascia and skin all blended by scar tissue. The peritoneum, recti muscles and the rectal sheath were sutured separately with silk, and the skin with silkworm-gut. Result: primary union. Discharged February 1 with solid scar and no hernia.

CASE 5.—Nellie Mc., age 28, admitted to Harlem Hospital December 21, 1897. April 1, 1897, an ovariectomy had been done. About the middle of November she noticed a slight bulging in the scar; this increased in size, and on admission, a rupture 3 inches in diameter was present. December 22, operation. The usual incisions were made on either side of the scar in sound skin. These incisions exposed the margins of the recti muscles. The peritoneum was opened alongside of the cicatrix, which, with some adherent omentum, was removed. The abdomen was closed with silk. The peritoneum, the recti, the sheath of these muscles, and the skin were sutured separately and continuously. Result: Primary union throughout. The patient was discharged January 11, 1898, with a firm scar.

CASE 6.—Kate S., age 40, domestic, admitted January 30, 1898, to Harlem Hospital. October, 1896, she had been admitted to a city hospital with diagnosis of rheumatism of the right hip. In a week's time an abscess appeared and ruptured. An incision was made for free drainage, and a quantity of pus was discharged. The scar from this incision ran along the crest of the ilium and down into the thigh across Poupart's ligament. September, 1897, a hernia appeared in the scar and gradually increased in size, but was not painful until January, 1898, then the swelling became tender, red, and warm. On being admitted there was found a well-marked hernia at the site of the former operation, together with a fluctuating swelling adjoining it on the outer posterior side, evidently containing pus. January 31, operation. An incision, parallel with the first one, was made into the abscess and a large quantity of pus evacuated. This pus-cavity was behind the peritoneum, and filled the iliac fossa, and extended upward into the flank. The abscess was undoubtedly due to a previous appendicitis. What appeared to be the stump of the appendix was found; although lying behind, it was not connected to the cecum, and was so much changed by surrounding granulation tissue that its origin could only be surmised. The abscess was thoroughly cureted and treated with H_2O_2 . Free drainage was secured by a large tube passed through the back external to the quadratus lumborum and above the iliac crest. The repair of the hernia was now undertaken. This was particularly difficult because the original incision had been made so close to the iliac crest that the abdominal muscles had been severed at their very origin, and being carried down into the thigh, Poupart's ligament had been cut away from the iliac spine. The abdominal muscles were freed near the marginal scar and sutured separately to the crest of the ilium. The transversalis and internal oblique more to the iliac fascia, the external oblique carried over the outer margin of the ilium and sutured firmly to the fascia lata. Poupart's ligament was reformed by this means, and by suturing the three muscles firmly to the fascia lata internal to the iliac spine. Silk was used for the muscles and silkworm-gut for the skin. The wound healed nicely. The abscess cavity was drained from the back until it closed. Three months after the operation the wound was solid, there was no sagging along Poupart's ligament, and no indications of a return of the hernia.

To make the consideration of this subject complete the conditions which predispose to the development of postoperative hernia must be mentioned, as well as the measures which should be used to minimize these factors at the time of the operation. The position and manner of the incision is of some consequence. Post-operative hernias are rare above the level of the umbilicus, and if present usually do not require operation; hence, incisions above this level will be ignored.

Regarding the placement and manner of making incisions in the lower abdominal zone I will state my own preferences. If the condition is to be reached by traversing the muscular layers and an aseptic operation can be probably performed, the gridiron incision is best. On the other hand, if pus is probably present a clean cut through the muscles without separation of their fibers is used. If the trouble is more centrally located the incision should be made in the median line. Division along the semilunar line or through the rectus muscle possesses no advantage over a median incision, but many disadvantages, as division of nerves, vessels, more trouble with hemorrhage, difficulty of readily and quickly enlarging the incisions, attending tearing and laceration of muscular tissue, and no guarantee that hernia will not result.

Make the incision sufficiently long to do quick work. The length of the incision does not seem to determine the rapidity of healing, nor does it determine the absence or presence of a hernia in the future. The chief factor in prevention depends upon the closure of the abdominal wound by the accurate and separate coaptation of the various layers, with some slowly absorbable material. There are two conditions which interfere with this important procedure. One is the necessity of maintaining drainage through the wound; the other, the state of the patient demanding such haste that the abdominal wall has to be closed quickly en masse.

Failure to properly close the peritoneum allows the viscera, usually the omentum and intestine, to become adherent to the wound. This arrests the free mobility of the intestines, and later on favors the development of a rupture. Abdominal drainage is less used now than formerly, because it has been demonstrated that in many instances the peritoneal cavity may be thoroughly cleansed by hydrogen peroxid and copious flushing with salt-solution, and complete closure of the wound made possible.

If drainage is necessary it can often be secured through some place even better than through the abdominal wound, as through the vagina in pelvic cases. However, some cases must be drained through the wound.

If gauze is used it should be wrapped around with rubber tissue, as suggested by Dr. Morris. This prevents troublesome adhesions to the muscular layers and abdominal viscera. With this drainage, or with tube drainage, the wound should be closed by separate sutures of the various layers close to the drain, in order to obtain primary union throughout the greater part of the incision.

A danger attending wound treatment in cases that must be drained is, that the raw surface of the wound may become infected, suppurate, primary union be prevented and a long cicatrix formed. Scar tissue is weak tissue, and if present in any considerable amount favors the development of a hernia. The treatment where hernia has resulted may be palliative or radical.

Palliative treatment by belts, bands, strapping, or trusses must be used in such individuals as will not submit to operation, and in those where an operation is contraindicated on account of the danger of using an anesthetic.

The radical or operative treatment depends for its success upon just two factors. First, isolation of the various layers forming the abdominal wall; and second, the accurate and separate union of the several layers for a sufficiently long time to obtain solid union.

Although the means for cure can be thus briefly and simply stated, like many other conditions, the execution is at times very difficult. A few practical directions may not come amiss:

1. Make the incisions on each side of the old scar in healthy skin, even though a large segment must be excised.

2. Look for and recognize the various muscular or fascial planes at a distance from their involvement in the scar, then incise the layer near the scar, but in normal tissue.

3. Divide the peritoneum far enough from the cicatrix so that its normal features are easily recognized.

4. Severe adhesions of the hernial sac to viscera or omentum, between ligatures when necessary.

5. An omental stump is to be covered up by rolling it into the omentum and keeping it there by a running suture of free catgut. Bare surfaces of intestine should be covered by bringing the peritoneal coats together. Subsequent adhesions are thus prevented.

6. Close the wound with chromic catgut.

It is taken for granted that all oozing has been arrested.

The peritoneum is united by a continuous strand of No. 0 chromic gut. The muscular layers by No. 1 if they are thin and weak, or No. 2 if thick and strong. These sutures are interrupted. They may be the ordinary through and through, mattress or Lembert, according to the individual requirements. The aim is to secure perfect coaptation of the divided muscular fibers. When there is tension, long relaxation sutures must be applied to remove the strain from the marginal ones.

The fascial layer is closed by continuous or interrupted stitches of No. 1 chromic, and the skin by a single strand of No. 0 applied subcutaneously.

The wound is protected by a light dressing and supported by rubber adhesive bands. Although in most of the cases reported silk was the suture-material, its use was necessary in the absence of suitable chromic gut, and my preference is for the latter, if perfectly fresh and sterile. The reasons for using a slowly absorbable material in all hernial and abdominal operations have been thoroughly established and need not be repeated here.

Rest in bed for at least 3 weeks should be observed when possible, because the line of union between the various layers cannot acquire the strength of the united tissues themselves in less time.

Use no truss afterwards. An abdominal belt without pads may be worn for comfort, but is not necessary.

Bristol Dispensary.—The annual report of the Bristol Dispensary for 1900, which has just been issued, states that 10,060 patients were treated during the year and that medical assistance was also given in 24 difficult midwifery cases. The committee add that the branch of the dispensary at Bedminster is much appreciated and that the number of patients attended is larger than in the preceding year.

ON THE DIETETIC MANAGEMENT OF TYPHOID FEVER.*

BY DAVID INGLIS, M.D.,

of Detroit, Mich.

AWAY back in the time when typhoid fever was first differentiated from the other continued fevers, some one originated the milk diet for this disease; and the medical profession, being subject to human frailties, has gone on accepting the milk diet as the proper treatment for typhoid fever, with a singular disregard of the facts, which pass under their observation, year after year. Theoretically, it would seem that physicians, in active practice, would reason out for themselves whether the milk diet were, really, what it is claimed to be or not; but it is a remarkable fact in all human history that men have accepted, for generations, not what they know to be true, but what they have assumed to be true, and so it has been with the medical profession and the milk diet in typhoid. It has been assumed that milk is a liquid and that it is readily assimilated and leaves little or nothing to pass through the bowels; and, upon this assumption, it has been further assumed that the nutritious qualities of the milk have served to keep up the patient's strength to the greatest possible degree, and that thus the two main indications in typhoid fever have been fulfilled; first, the avoidance of irritation of the ulcerated Peyer's patches, and therefore the prevention of hemorrhage, and, second, the maintenance of the general bodily nutrition. These assumptions have been quietly accepted by countless thousands of physicians, notwithstanding the fact that, at the termination of the fever, the patient has been found to be emaciated to an extreme degree, demonstrating visibly that the bodily nutrition has not been maintained to any high degree, but quite the contrary.

Let us take the first assumption, that milk is a liquid which is readily absorbed and leaves little or no detritus to pass through the intestines. The fact is that the serous portion of the milk is absorbed through the gastric mucous membrane, but this constitutes but a small part of the bulk of the milk. The casein of the milk is rapidly turned into a solid, which is not digested in the stomach but is passed on into the intestines. When a patient has a pretty steady diarrhea he usually succeeds in passing out the casein in small flocculent curds, and, as long as he succeeds in doing so, he remains tolerably safe from one of the dangers of this deceptive fluid. If, however, he does not have a sufficiently active diarrhea the casein is liable to form masses of scyballae, not only in the large intestine but high up in the small intestine. Wilson, writing in the *Columbus Medical Journal*, says that, in a number of postmortems on typhoid-fever cases, he had always found curds of undigested milk in the stomach and portions of these curds in the small bowel, where they were forming ideal foci for fermentation and breeding-grounds for various microbes. Every physician who has had an extensive experience in typhoid fever is familiar with that exceedingly unpleasant complication which occurs, by no means unfrequently, toward the end of the fever, in cases in which the early diarrhea had stopped, or which occurs, even during the progress of the fever, in cases uncomplicated by milk diarrhea, the condition in which the rectum and colon become filled with impacted feces. The physician who has once scooped out

from the rectum the dense, hard masses, so hard, in many instances, that, before attempting to break them up and remove them, it is necessary to soften them by injections of oil or soapsuds, every physician who has had this experience knows that this dense mass consists of nothing, practically, but milk. It is an entire mistake to regard milk as a liquid in diet. It is a liquid in the tumbler, but we ought always to think of it as solid food. It becomes a solid in the stomach, it enters the small intestine a solid, and it passes through a solid. If the original assumption be true, that it is wise to feed the patient so that there shall be as little as possible of irritating detritus passing down over the ulcerated glands, then certainly milk does not fill the requirements.

Not only is the milk diet, in typhoid fever, logically unsound because of the large amount of solid substance which it sends down through the small intestine, where it is liable to act as an irritant, but it is a dangerous diet because it forms an admirable culture-medium for various bacteria. That it is an admirable medium for the spread of the specific bacillus of typhoid fever is undoubted. Whenever an epidemic breaks out and we attempt to trace the source of the intoxication, we search, first, for a defective water-supply, and, if we do not find the source of contamination there, we immediately begin to follow the routes of the milk men. A large number of epidemics have been traced, accurately following a single milkman's route. If the milk can carry the poison into the patient in the first place, the large amount of undigested residue of solid milk, in the small intestines, would seem to form an admirable breeding-place for the further development of the specific germ of typhoid, but the question is a much wider one than simply the spreading of typhoid bacilli. At a recent meeting of the Detroit Academy of Medicine Dr. Dock read a paper on the treatment of typhoid fever. In the discussion I brought up the point just alluded to, and Dr. Dock's reply was to the effect that, after the first intoxication, in typhoid fever, the bacillus of Eberth was found, not so much in the intestinal canal or on the mucous membrane, but in the deeper structures of the intestinal wall, in the intestinal and mesenteric glands, as well as in more distant glandular structures. It was argued that, therefore, the attempt to produce intestinal asepsis was useless, as the specific bacilli were out of reach. Such an argument, while it may be technically correct, loses sight of a very essential series of facts. I suppose that no one would, for a moment, assert that all of the bacilli of Eberth left the intestine and were taken up in the glandular structures, for, were this so, there would not be the slightest danger of conveying the disease to others, by means of the dejecta of a typhoid-fever patient. Now the fact is that, throughout the disease, the stools of the patient contain the specific germs in such quantities that we all thoroughly understand that it is from this source—practically from this source only—that the disease is propagated to others; it therefore is demonstrable that the specific bacilli of the disease remain in the intestinal canal, and there is every reason to believe that masses of undigested milk may very easily form a breeding ground for the bacilli, and so furnish a constant intoxication of the patient; but, even were there no typhoid bacilli left in the intestinal canal, there are other bacilli which will thrive with equal rapidity in milk, and there is every reason to believe that not only in typhoid fever but in many other diseases the real

* Read before the Detroit Academy of Medicine.

danger to the patient proceeds from the secondary intoxication. Stop, for a moment, to consider the phenomena of an ordinary case of consumption. The patient is infected with the tubercle bacillus. Under ordinary circumstances, as long as the infection is purely tuberculous, the patient's progress, from bad to worse, is but slow. He has, indeed, fever, cough, emaciation, and a small amount of expectoration, often almost none; so he may continue for a considerable time, slowly getting worse. Once let some portion of the lung-substance become necrosed and a secondary streptococcus infection take place, notice what a rapid change occurs. He now develops hectic fever, night-sweats, profuse expectoration, diarrhea. It might almost be said that the great danger of the tuberculous patient was that of a streptococcus infection. It is the secondary infection that starts him on the rapid downward course. Take, again, the phenomena of diphtheria. The primary infection is by the Löffler bacillus. The exudate in the throat is the result of the primary infection. While it is true that our efforts ought to be directed to overcoming the primary infection with all possible speed, does any physician feel justified in neglecting attention to the exudate? Not at all. Indeed, he recognizes that the exudate forms a focus for a constant reinfection of the patient. Not only does the exudate form a focus of reinfection by the Löffler bacillus, but by the streptococcus as well. And again there is reason to believe that no small part of the danger of the diphtheric patient arises from the secondary infection. We ought to keep precisely the same reasoning in mind in the management of typhoid fever. It does not seem a question of the primary infection of Eberth's bacillus alone, but anything which facilitates a constant reinfection by the Eberth bacillus or a secondary infection by streptococci or the colon bacilli, adds enormously to the patient's dangers.

On these grounds, then, it seems to me that we have made a radical mistake in feeding milk to typhoid-fever patients. Osborne, in an article in *THE PHILADELPHIA MEDICAL JOURNAL*, in December, 1899, has this to say:

"In typhoid fever, constipation keeps the partially digested milk or other nutriment long in the intestines, the mucus and ulcerative sloughs remain in situ, and thus beautiful culture grounds for all sorts of bacilli and cocci are formed, while in addition, the colon bacillus adds its toxins to the rest. Next, fermentation increases and gas is formed, and tympanites occurs with its discomfort and dangers of perforation and of hemorrhage from distention; meanwhile the action of the heart will be impaired as a consequence of abdominal distention. All of this increases the fever and the cerebral toxemia. If one has a doubt of what such bowel stoppage causes, he has but to recall instances in which a case of irregular chills, heavily coated tongue, profound headache, high and continued fever, concentrated urine, constipation, and tympanites has been proved, by absence of the malarial plasmodium from the blood and the negative Widal serum reaction, to be neither malarial nor typhoid, but a pure case of bowel infection."

Let us return now to the other assumption of the advantages of milk diet, to wit: that milk keeps up the nutrition of the patient to the highest possible degree. Does it? Let any man who has carried his typhoid-fever patient through, giving abundance of milk, and who sees his patient reduced to a skeleton, ask himself the question, "does it?" The fact is it does not. The patient comes out at the end of the fever emaciated until he could hardly become emaciated any further. His pulse is weak; it could not become much weaker and the patient live. It would certainly seem that no

other food could have brought the patient to a condition any worse, as far as his nutrition is concerned. I think the physician, looking at the emaciated typhoid skeleton, might even ask himself, "How much thinner would my patient have been if he had had no food whatever?" It would seem, therefore, that the primary assumptions so commonly accepted on close examination are proven to be wrong one and all. Now there is another side. Before the patient calls the doctor, in typhoid fever, he usually has a period of from a week to ten days of general malaise during which he has a moderate degree of fever, a good deal of headache, and a moderate diarrhea, if any; he is sick, but he is not very sick. Finally the doctor is called. The patient is put to bed and measures are taken, one way or another, to moderate the fever. Theoretically he ought at once to begin to be somewhat better, or, at the very least, he ought not to grow rapidly worse, for now, lying in bed, he ought to save his strength and abate his fever, even if nothing were done for him. What happens? The officious doctor, eager to keep up his patient's strength, begins to insist on his taking considerable quantities of milk. The patient, led by nature's own indication, has been eating practically nothing. Now the fever begins to climb, step by step, day by day, until within three or four days it reaches its high point, and now the physician enters upon a long fight in which he endeavors to keep the fever within moderate bounds. It may be that the patient is put into the bath and the temperature is forced down, only to run rapidly up in the next two or three hours, when another bath is given. So the temperature see-saws, inevitably rising as soon as the effect of the bath has passed off, and meantime the patient is being fed casein, although the doctor knows very well that the patient's digestive powers, as far as his stomach is concerned, have practically ceased, and the digestive power of his small intestine is even more precarious. Nevertheless down goes the casein.

It has been my amusement to visit Mt. Clemens, the "Mecca" of rheumatic patients from all parts of the United States. I have seen patients who had scraped together, with great difficulty, enough money to come to Mt. Clemens, take a bath every morning, be rubbed, scrubbed, sweated, in a vigorous attempt to eliminate the rheumatic poison, and then, three times a day, sit down in the dining-room, study over the bill of fare, in which the hotel-keeper had provided an admirable menu consisting for the most part of meat and eggs, and then I have seen the patient eat more nitrogenous food at one meal than he could wash out of him by the bath the next morning. It seemed a most astonishing thing to see a man, three times a day, putting into himself the very substances out of which is formed the poison which he is laboriously trying to get out of himself. Precisely analogous is the process of forcing food on our typhoid patients. The primary infection of the typhoid bacillus takes place by way of the sound mucous membrane. When the bacilli have begun to fill up the glandular structures connected with the intestine, the disease is established and must take its course, but without a fresh and continued infection it would seem reasonable to believe that the period of activity of the bacilli would come to an end within a reasonable time. If the intestines were emptied, as far as possible of all substances, which could form a culture ground for bacilli of any kind, the process of reinfection would, thereby, be reduced to a minimum. While the primary infection was pursuing its course, a certain waste of

the tissues of the body would undoubtedly take place, but the probability is, that the febrile process would very soon become limited, by the absence of pabulum. In so far as the serous part of the milk is absorbed and, in so far as a portion of the casein is digested and absorbed, it is a question deserving of careful investigation, whether these foodstuffs do not simply serve to feed the fever. That the feeding of fevers in the so-called supporting treatment, is devoid of the striking advantages claimed for it, is shown by the statistics of the Massachusetts General Hospital. In these the mortality is shown to have been practically the same in the days when purging, bleeding, and low diet were employed, as it is when the feeding and supporting treatment are used. Now the old treatment of low diet included bleeding and purging. Our medical ancestors were as dangerous to their patients as we are to ours, only in a different way. If they had been content to let their patients have a low diet and lots of pure air and pure water they would, I think we will all agree, have had better results had they omitted the bleeding and used only so much purging as would keep the intestines fairly free from putrefying contents. They had a pretty good idea at the bottom of their purging process, but they overdid it. When the reaction came we went too far the other way, and, in a desperate attempt to support our patients, we also have sinned by overdoing.

A curious series of experiments on animals has been made, which has shown that feeding does not increase the vital resistance in fevers. Inoculated animals were found to survive any given infection, with little or no food better than those fed liberally. I know that it takes nerve to see a typhoid-fever patient gradually wasting both strength and flesh as the fever goes on, and refrain from putting, what to a well man is nourishing food, into the patient. We do not see the dark red stomach, containing far more mucus than gastric juice; we cannot compel our imaginations to make real to us the swollen, cyanosed, almost or quite necrotic mucous membrane of the small intestine. If we could imagine these internal conditions so vividly that it was all as clear to us as the dusky face, the shrunken arms and legs, the hollow eyes, it would be easier for us to resist the impulse to put a lot of stuff down out of sight and hope for the best.

It has been my fortune to advocate the principles I now contend for, in consultation at the bedside. The doctor says: "Yes, doctor, I believe you are right in theory; I can see that the stomach is practically unable to digest food, that the intestinal mucous membrane not only has long since lost its normal function but is apt to be damaged by irritant substances and putrefying ones; you may be right that the fire of the fever would be less intense and would burn down sooner if we didn't keep piling on fuel, but just look at the patient! See how thin he is! How weak his pulse! Some time I'd like to discuss your theory with you, but I guess this time I will go on feeding."

It takes nerve to take an infant suffering from cholera infantum, take it away from the mother's breast, cut off cow's milk, or food of any kind, and keep the baby on sterilized water and Epsom salts until the nearest approach possible to intestinal asepsis is secured, but, fortunately, the profession has learned that degree of courage.

I am well aware of the limitations of my own personal experience in typhoid fever, but at least I have

seen this. I have seen patients whose fever kept springing up after the bath like a steel spring, patients whose brains were so poisoned that delirium was deepening into coma, come out into moderate fever and a clear head within 48 hours after the forced feeding was stopped and a water diet instituted.

We are oppressed by this fear of starvation. Starvation is a slow process. Dr. Tanner demonstrated that 40 days' starvation is endurable provided the patient drinks plenty of pure water.

The ideal diet for typhoid fever is pure water in abundance. This will keep the excretions by skin, lungs, kidneys, and liver up to their best, and our typhoid patients need to keep all means of elimination of poison in fullest activity, providing it be not a prostrating activity. The action of kidneys, liver, and skin induced by superabundant water is never prostrating. This cannot be said of action induced by drugs. It is not enough to give the patient as much water as he may happen to crave, we must use our scientific imagination to picture the very large quantity of water which goes out by the lungs; notice how quickly the moistened tongue becomes parched; we must realize the evaporation from the skin; consider the diarrhea and the urinary needs; then put in water enough to keep all these in full activity.

People have imbibed enough of current medical opinion to make it difficult to stop our present dangerous overfeeding. Even were the attending physician convinced of the safety of the pure water diet, the friends will insist that the patient's strength must be kept up. In such cases any of the best advertised meat-juice foods (so-called) can be utilized. They contain little real food value, and are, fortunately, mostly absorbed in the stomach, and so leave little or no detritus to go through the bowels. There comes a time in the course of the fever when the patient's appetite returns. This is always a difficult period. Pressure by both the patient and the patient's friends is very great. It is hard to resist the cry for all kinds of food and lots of it, yet there is probably no man who reads this who has not had the bitter experience of seeing his patient quickly relapse after some newly-tried indulgence in food. It seems to me that the best rule to follow is this: Give such foods as are most completely digested and absorbed in the stomach; keep steadily in mind that while the stomach may be acting but poorly, the intestinal condition is far worse. Still we should send down from the stomach as little detritus as possible. A tender lamb chop or a poached egg is safer than a tumbler of milk; safer now, safer all the way through.

One thing I wish to add in the matter of stimulation. Time has been when a convalescing typhoid patient drank alcohol in great quantities. The practice seems now largely gone by, and fortunately so, yet throughout these cases the physician knows the need and the value of an occasional stimulant. For a long time I have used, instead of alcohol, a small drink of good coffee. Those of us who know how a cup of coffee at—say from two to four in the afternoon, will keep us awake till two o'clock in the morning, know that the stimulant effect of coffee is not transient like that of alcohol, but lasts hour after hour—six, eight, ten hours. Now, what a typhoid convalescent needs is not a fillip which picks him up and drops him down again, he needs a good, steady, lasting lift, and coffee will give it to him. Don't have the friends give him watery coffee; a delicate after-dinner coffeecup full of good coffee with

cream and sugar will taste good and do good, and keep on doing good.

One more practical point. I have urged that such foods as are given should be readily absorbed by the gastric mucous membrane; there is one food of which we are apt to think too little—sugar—we are apt to think of it as simply a means of sweetening foods; in reality it is highly nutritious—no other hydrocarbon is more promptly and easily absorbed—it leaves no detritus whatever. A man with muscles, tired from labor, can recuperate rapidly on sugar. A typhoid patient can take it up rapidly. I have ventured to present these thoughts on the dietetic treatment of typhoid fever in the hope that they may stimulate discussion and induce men whose daily practice gives them large opportunity to observe, to put these ideas to a thorough test.

SUDDEN DEATH IN PLEURISY.

With Report of a Case.

By CHARLES LEWIS ALLEN, M.D.,

Pathologist and Assistant Physician, New Jersey State Hospital at Trenton.

SUDDEN death in pleurisy, at any rate apart from operative procedure, is certainly quite exceptional. Trousseau stated that in a hospital and civil practice of 19 years, he saw only 3 cases. Few, if any other observers have encountered a greater number, hence it seems proper to put on record the following case, which presents some interesting and unusual features:

F. S., 44 years of age, a powerfully built and well-nourished man, insane for about 12 years, and at the time of his last illness, a terminal dement, never speaking, so unable to give any account of himself, on October 1, 1900, was noticed to have lost his appetite, and appeared ill. His temperature was found to be 99° F., his tongue slightly furred, but a physical examination was negative, and no other symptoms could be elicited. He was given a calomel purge. On October 2, his condition appeared unchanged. Temperature A.M., 99°, P.M., 100°. On October 3 he seemed better. Morning temperature 98.5°; afternoon temperature, 99°. Nothing wrong was noticed during the night, but on the morning of October 4 the attendant found that he had soiled his bed, something quite unusual for him, and when he was gotten up to be cleansed, he appeared quite weak. At about 8 40 A.M., he was noticed to be blue and collapsed; he vomited, his bowels moved involuntarily, and he had a convulsion. Responding at once to a summons, I found him cyanotic and pulseless, his skin cold and covered with sweat, his respiration rapid and labored. A few coarse rales could be heard over the left lung, none over the right. The heart-sounds were inaudible. Strychnin was at once administered hypodermically, but he was dead before some hot bottles which were being prepared could be applied.

An autopsy, made 6 hours after death, showed the following conditions: The brain, apart from some adhesions of the dura along the superior longitudinal sinus, and slight milkiness in places of the pia arachnoid, presented macroscopically nothing abnormal. The left pleural cavity contained about 180 cc. of slightly blood-stained serum. The left lung showed old and very firm adhesions over its lower portion. The left pulmonary artery was completely filled by very firm dark clot, which extended into its larger divisions. The right lung was so firmly adherent over its whole area that it could not be removed without tearing it. The greater part of the adhesions were old, but there was some recent pleurisy with fresh adhesions over its anterior surface. No fluid. Toward the lower portion of the inner border of the right upper lobe, there were two hemorrhagic infarcts, each about the size of a pigeon's egg. The lumen of the right pulmonary artery was free, but its medium-sized branches were filled with firm, dark clots. Both lungs were deeply congested and somewhat edematous. At both apices there

were several areas of fibrous induration containing in their centers a calcareous deposit, apparently healed tuberculosis. The bronchial glands were enlarged and deeply pigmented. The pericardium appeared healthy. Its cavity contained about 30 cc. of blood-stained serum. The heart was flabby, but its muscle appeared normal. Each ventricle contained a few soft clots, some dark and some pale. The valves were normal. The peritoneal cavity contained a small amount of clear serum. The liver was congested. The stomach showed chronic gastritis. The other organs were normal. The microscopical examination gave no further information, except to show that the kidneys were not diseased.

It would seem as if the pleurisy should have been diagnosed before death, but it is to be remembered that the patient was demented, made no complaint, and it was entirely impossible to get his cooperation. With insane individuals we have often to be content with a very imperfect physical examination. Again, his symptoms pointed rather to a mild gastrointestinal catarrh, than to any disease of the lungs, and as he seemed to be improving, his chest was not examined again after the first day.

Gee,¹ in speaking of sudden death in pleurisy, gives three causes for this accident: (1) Suffocation from rupture of an empyema into the lung; (2) sudden development of pulmonary edema; (3) thrombosis or embolism of the pulmonary artery, or thrombosis of the right heart, the immense majority of all cases being due to this last cause. By some authors, a kinking of the aorta or vena cava through displacement of the heart by the effusion, has been held accountable for the occurrence of thrombosis or embolism. This view has been combated by Leichtenstern,² who, from experiments upon the cadaver, has concluded that it is impossible for enough "kinking" of the vessels to cause an obstruction to be produced through the filling of the pleural cavity with fluid. It is, however, pointed out by Rosenbach,³ who rather favors the vessel-kinking theory, that it is hardly fair to assume from experiments upon cadavers that the production of kinking is impossible in the living subject, in whom the condition of the vessels, etc., is entirely different.

The occurrence of sudden death during or after washing out the pleural cavity was not unknown when this practice was commoner than it is today. Perhaps in this case it is to be explained by the entrance into the circulation of a flake of fibrin loosened by the washing.

Of 10 cases of which Leichtenstern² gives a summary, 9 were due to thrombosis, and 1 to embolism. As favoring these conditions, this author gives the following:

1. Slowing of the circulation on account of obstruction due to compression of the lungs and weakening of the heart by the continued fever.

2. The pressure on the heart and vessels exceeding the atmospheric pressure, the aspiration in diastole is much diminished.

3. The aspiratory power of the compressed lung is diminished or lost.

In his experience, in the majority of cases of sudden death, the pleurisy was right-sided. In another class of cases death has been due to cerebral embolism. In still others to causes not directly connected with the pleurisy, while there yet remain cases in which the autopsy furnished no information as to the cause of death. Weill⁴ calls attention to the fact that in some cases death may be due to myocardial disease, and reports an instance of this which he himself has observed. In none of the cases of which I have been

able to find a report has effusion been absent, though in some it was of moderate extent. In the case here mentioned the effusion was very small indeed, in fact, it seems to me probable that the fluid found in the left pleural, the pericardial and the peritoneal cavities was only exuded during the death agony. There was no evidence of recent pleurisy on the left side. The most prominent condition was the great extent and firmness of the pleural adhesions. That complete adherence of one lung, however, need not necessarily cause much embarrassment of respiration or circulation is shown by a case reported by Warner.⁵

It seems to me that in the above case of F. S. the following sequence of events is probable. During the night, or early morning, a flake of fibrin was absorbed from the area of fresh pleurisy in the right lung. This being carried to the pulmonary vein, lodged there, and produced a gradual thrombosis which caused a fatal termination several hours later. This case certainly lends no support to the theory of vascular kinking, since, though the adhesions were very extensive, there was no contraction of the chest and the heart was not displaced.

Subphrenic Abscess.—Krohne (*Deutsche Med. Woch.*) reports a case occurring in a child 7 years of age, which, on account of its difficult diagnosis and etiological factors, is very interesting. About 2 years previous to the present illness the child suffered from a purulent otitis of the middle ear, this caused mastoid disease, requiring operation, with removal of some necrosed bone; after recovering from this the child enjoyed fairly good health until June, when it developed a perityphlitis, with some localized peritonitis which yielded easily. About the end of July the child developed a hectic condition with concomitant symptoms and a tumor above the liver on the right side; a week later a **purulent bronchitis** with the expectoration of a foul pus developed, and it looked as if collapse would soon follow. The diagnosis was then clear and Krohne decided to operate. An incision 6 cm. long was made on a line with the ribs about the level of the xiphoid, and about a cup of pus escaped, the adhesions (between pleura and lung) gave way and **air and pus entered the pleural cavity**. The abscess was packed with iodoform gauze and washed with $\frac{1}{2}\%$ creolin solution until healed. The cause of this abscess does not seem clear; was the infection from the ear or the perityphlitis? [W.S.N.]

Inguinal Hernia.—In a paper read by B. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio, before the Medical Society of the State of New York, Albany, January 29, 1901, Dr. Ricketts gives the most complete and comprehensive description of the anatomy of the parts involved in inguinal hernia to be found in any work. In fact, it embodies the researches of all the best anatomists and specialists. He criticises the use of the word canal in this connection. He claims that, etymologically and anatomically, the use of the word canal is wrong. Ring is the proper word. A circular letter was sent to over 100 prominent surgeons. Many interesting facts can be deduced from the replies received. Thirty-four surgeons gave an approximate percentage of recurrence in their practice; this percentage varies from 1 to 15%. This last percent agrees with the figures of Prof. Girard, of Berne, who claims that the percentage of recurrence in Europe will amount to 15%. The percentage will average 5.58%, based on 6,027 operations by 34 surgeons. From statements contained in letters received in answer to the circular, it is fair to infer that only one-half of the total number of operations were reported. This would bring the percentage up to near

15%. These letters show that infection is less frequent and that there is no recurrence when wire or silkworm-gut is used in the Phelps, Halsted, or Abbe method of operation. The doctor bears unequivocal testimony to the success of the Phelps operation; he employs it in his practice, and considers it to be the ideal one. It is the only one that insures a successful and a permanent cure. The doctor agrees with Abbe that silver wire or silkworm-gut is to be employed in preference to absorbable sutures. He does not believe that suppurative has anything to do with causing recurrence; the real cause, or rather causes, of relapse of recurrence are deficient origin (attachment) of the internal oblique muscle, pressure of truss (where one has been worn), length of time that hernia has existed, lack of nerve and blood supply, and intraabdominal pressure rupturing the cicatrix; the latter factor can be disregarded if the Phelps method is employed, because if the wire mattress is once placed properly there is no possibility of relapse by a rupture from the intraabdominal pressure. The doctor doubts the doctrine advanced by some writers, that varicocele is a causative factor in inguinal hernia. He properly holds that all herniotomies should be regarded as modified laparotomies. The paper closes with several pertinent questions: Is there anything in the habits engendered by our rapidly-advancing civilization that is conducive to the production of hernia? Is man progressing toward perfection morphologically, or degenerating? The doctor refers to an edict of the Emperor Constantine, forbidding operations which involve the loss of the cord and testicle, for fear that the population of the country would suffer.

Abscess of the Liver Following Typhoid Fever.

—Emile Cassuto (*Gaz. Heb. de Méd. et de Chirur.*, January 6, 1901, 48me Année, No. 12). (Paris Thesis, 1899-1900, No. 626.) Abscess of the liver supervenes very rarely in the course of **typhoid fever**, particularly in Europe, but occasionally in tropical or intertropical countries. Cassuto, who has made a very complete study of these cases, shows that hepatic suppurations of typhoid origin from the anatomopathologic point of view present 2 principal varieties. The first is characterized by the small size and the multiplicity of the foci, by the multiple metastatic foci secondary to suppuration in some other part of the body, by a diffuse form of periangiocolitis of typhoid origin following ulceration of the bile paths, by a diffuse form of peripylephlebitis of typhoid origin consecutive to a juxta-intestinal suppuration, or to an ulcerogangrenous lesion of the intestine, particularly of the appendix. The second form is exactly like the circumscribed, suppurative hepatitis of dysenteric origin and consists of single purulent collections. In such cases there are no ulcerogangrenous lesions of the intestine, no purulent foci near the intestines, and nothing in the appendix. The intestinal typhoid ulcerations are, in these cases, well on the way toward being cleared and in the gangrenous process can be demonstrated in their neighborhood. The infecting germs coming from the typhoid ulcers in the intestine may reach the liver in three ways: (1) By the biliary paths; (2) by the arteries, and (3) by the portal vein. In all cases of multiple abscess due to pylephlebitis or to ulcerogangrenous lesions of the intestines, the pus in the liver presents the characters of fetid gangrenous pus. Also, in cases of multiple abscess of the liver of typhoid origin following a pylephlebitis, a juxta-intestinal suppuration, or an ulcerogangrenous lesion of the intestine, the pus probably contains microorganisms that are strictly anaerobic associated with the typhoid bacillus. In 2 cases of single abscess, bacteriologic examination, as well as direct microscopic examination of the pus, showed the presence of a pure culture of the bacillus of Eberth in one case; and the bacillus of Eberth associated with very rare colonies of staphylococci in the other case. The bacillus of Eberth alone is capable of producing pus in the hepatic tissue. But it is to be noted that this bacillus seems to lose much of its virulence in that organ. The symptoms of suppurative hepatitis of typhoid origin are about the same as those of suppurative hepatitis in general. The diagnosis of this complication of typhoid fever is often impossible. Nevertheless, if the practitioner remembers the possibility of its occurrence and makes daily examinations of the liver of the patient suffering from typhoid fever, he will probably be able to diagnose the condition occasionally. The existence of an empyema containing the bacillus of Eberth ought to draw the attention to the liver immediately. [J.M.S.]

Sanitation and Progress.—In his address before the Pan-American Medical Congress, just held in Cuba, Surgeon-General Wyman gives expression to some mature thoughts which are evidently the results of his wide experience. He emphasizes especially the need of better correlation between municipal, national and international authorities in the great undertaking of the elimination of contagious diseases. He is impressed with the fact that we are seriously lacking in the proper efforts to suppress many suppressible diseases. Among the diseases which he mentions as well under control are smallpox especially, and diphtheria, while he thinks that we are certainly on the verge of the discovery of specific remedies for both tuberculosis and typhoid fever. Why then do these and so many diseases persist? It is that sanitary advance has not kept pace with scientific knowledge. It is also evident that this scientific knowledge is not so widely diffused as it should be, even among those in whom we have a right to expect it.

With regard to cities, a stronger public sentiment should be created in favor of municipal cleanliness, which should rank as one of the foremost objects of municipal government. Dr. Wyman calls attention to the fact, which we sometimes deplore as a necessity of our form of government, that this field of municipal cleanliness is not a field for the national Government, but distinctly for the States and cities, and that the degree of sanitary excellence in our cities is a fair exponent of their civilization and culture. Our cities in this respect are striking illustrations of the fact that their governments are the governments of the people. It is therefore necessary to cultivate among the people a knowledge of sanitary science and a demand for such knowledge in municipal authorities.

Dr. Wyman sees no reason why slums should be allowed in any city. Too much attention is paid to public parks and handsome municipal buildings, whereas the most-needed improvements are in the alleys, around the docks, and in the tenement districts. Another strong plea for sanitation lies in the promise which it would give of getting rid of quarantine. The time is at hand when we must consider the necessity of ridding ourselves of these restrictions upon commerce. It must be evident to all intelligent observers that many quarantine methods, especially those still used in the more rural districts, are antiquated, oppressive, and even absurd, and Dr. Wyman does well to call

attention to their defects. When a large number of cabin passengers, all of them in good health, are held on board a steamer in the upper cabin because of one case of infectious disease in the steerage, they may reflect that their detention is due primarily to the faulty sanitation of some miserable portion of some foreign city, and they may receive thereby a demonstration of their personal interest in sanitary science. Another urgent need is to decry, and punish if possible, municipal deception either in the concealment of contagious disease or by reports giving a sense of false security to other communities. Municipal morality in such cases is evidently on as low a grade as municipal sanitary science.

Finally, Dr. Wyman calls attention to the urgent necessity of having our legislators more thoroughly trained in the knowledge of sanitary science. We need a class of men who are at one and the same time versed in the law, who are skilled in framing the laws, and who are also familiar with the requirements of sanitary science. It is to be hoped that Dr. Wyman's views, as expressed in his address, will be given wide publicity. They need to be disseminated among people at large even more than among the medical profession. Public intelligence alone can make effective the methods of true sanitation. This seems a hopeless task sometimes, when we consider the credulity of the people with reference to the fundamental questions of health and disease, and it is only by the dissemination of such knowledge as Dr. Wyman has presented in his address that we can hope for widespread and enduring results.

Unsolved Problems of Chemistry.—According to Professor Remsen, of Johns Hopkins University, who appears in a popular article in one of the magazines, we have little positive knowledge of starch, cellulose, proteids, and protoplasm, and the outlook is not very brilliant for the improvement of this knowledge in the near future. As so much of the hope of improvement in practical medical science depends upon advances made in bio-chemistry, we greet this declaration of Professor Remsen with considerable regret. Of all the substances that go to make up animal tissue the chemist is most familiar with the fats. He can take carbon, hydrogen, and oxygen in the laboratory and can construct fats as they occur in animals—not that the chemist often does this in fact, but that he could do it if he took the

time and trouble. Sugar is not entirely an unsolved problem, especially since the labors of Fischer, of Berlin, for in its simpler form it, too, can be made in the laboratory. But with starch and cellulose the case is different. This latter substance, cellulose, is the basis of plants. It contains only the three elements, carbon, hydrogen, and oxygen, and yet the chemist is still ignorant of how these substances are combined to make cellulose. The proteids are, if anything, a still greater mystery. As they are the chief constituents of muscle, nerve, and blood, it is most essential that they should be understood. But Professor Remsen seems to think that they will be unsolved problems for generations to come.

Of all the problems of synthetic chemistry the most important relates to the construction of protoplasm. This is the living tissue. It is derived from a fat, a proteid, and a hydrocarbon, and its exact construction (that which renders it the seat of life) is unknown. This problem must be solved before we can have a real scientific knowledge of what constitutes life. Professor Remsen is rather pessimistic, and thinks that for a long while we shall have to be content with small returns from our labors in these fields.

The Courage of One's Opinion.—One of our daily contemporaries in this city wants to have the Christian Scientists inoculated with the infectious diseases. This is not for the purpose of getting rid of the Christian Scientists (which would be a consummation devoutly to be wished, if some less radical method were employed) but merely for the purpose of converting these fanatics and convincing them of the reality of disease. With a cynicism which we should not like to imitate, this worldly-minded contemporary suggests that one Christian Scientist take into his system the "seeds" of tuberculosis; another, the bacillus of Asiatic cholera; another, the microbe of tetanus; and another still, the parasite of malaria. If there is no truth in the discoveries of bacteriology then, says our neighbor, every one of these supreme tests would fail and the luminous truths of Christian Science would shine before the world.

With these shocking suggestions we are not in accord, and we quote them with reprobation, but we cannot refrain from reminding our readers that the scheme is not altogether new. The late Professor Gross adopted the same method of criticism on one occasion when he suggested that a proper test for a non-belief in the existence of hydrophobia would be for the doubter to allow himself to be bitten by a mad dog. Such suggestions are never taken seriously, and it is needless to say that they are never adopted. We should like to know, however, of what use it would be to convert a Christian Scientist by giving him tetanus or Asiatic cholera? He would probably not live long enough to profit by his experience. But the chief logical defect

in the plan, so far as it relates to the Christian Scientists, is that it ignores one of the very elements of ignorance, superstition and delusional insanity. These mental states are essentially illogical; they do not yield to the ordinary processes of reasoning, because the faculty of reason is undeveloped or impotent. The more proof there is presented, the more obstinacy there is displayed. If it were not for the injuries done to innocent victims, it would probably be just as well to let this cult go unopposed in the belief that it would some day die a natural death. But these injuries cry aloud for the suppression of the whole mischievous sect.

The Pneumonias of Influenza.—According to Leichtenstern (Nothnagel's *Special Pathology and Therapy*, Vol. IV, Part 1), "Pneumonia is the most frequent and most important complication of influenza."

A thorough investigation of the history of influenza epidemics proves that the complication, pneumonia (in some variety) has never been absent. This was noted as early as 1580 by Bockelius (quoted by Ruhemann) and particularly emphasized by Sydenham in 1675. It was for the most part taken for granted that bronchopneumonia arose, as a result of the severe bronchitis (the inflammatory process spreading by continuity of structure), or that it was a form of mixed or simultaneous infection by the specific causes of influenza and pneumonia.

Both views are undoubtedly correct, and were this the only variety of pneumonia complicating influenza, the diagnosis in the majority of cases would be an exceedingly simple one. There is, however, another variety first hinted at by Gray in 1782, and particularly described by Leichtenstern in December, 1889, of "a primary influenza pneumonia," a form of inflammation of the lungs due to the bacillus of Pfeiffer and its toxins, which occasionally even makes its appearance simultaneously with the other phenomena of influenza, but more frequently arises at the acme of the disease. Leichtenstern calls this "the pneumonic form of influenza."

The accuracy of this assertion was proven two years later by Pfeiffer and others, who found in the pneumonic exudates (in the alveolar lumen and alveolar septum, especially enclosed in the round cells) the specific bacilli of influenza in "extraordinary amounts." Pfeiffer says: "In smear cultures prepared from secretions of the trachea and larynx a mixture of various microorganisms was found, especially streptococci and diplococci, etc., but even here the bacillus of influenza was found to outnumber the other bacteria. In the large bronchi, all other bacteria (except the bacillus of influenza) gradually disappear, and as the finer bronchi are reached, especially when a purulent secretion is present, and in the pulmonary tissue, the bacillus of influenza is alone found to be present."

According to Pfeiffer, Beck, and Wassermann, the

anatomical form of this true influenza pneumonia is an exclusively catarrhal one. It is no doubt true that the majority of the pneumonias are of the broncho-pneumonic form, nevertheless there can be no question that numerous broncho-pneumonias of "grippal" origin are of a mixed form due to the presence of streptococci, and perhaps diplococci also, which may even in some cases outnumber the Pfeiffer bacillus. Only in this manner can we explain the numerous cases of pneumonia occurring in the pandemic of 1889-90, during which this condition was frequently observed. Albu even regards this mixed infection as pathognomonic of pneumonia due to influenza (*Deutsche med. Wochenschr.*, 1894, No. 7). Besides this purely catarrhal (broncho-pneumonic) form, the croupous form is also frequently observed, and a third variety of mixed pneumonia, that is, a catarrhal-croupous form, or, as Leichtenstern proposes to call it, a "cellular-fibrous" variety.

He bases his opinion upon postmortem findings in which mixed and transitional forms are found, lobar and lobular infiltrates, whose correct pathological classification, whether catarrhal or croupous, is both macroscopically and microscopically exceedingly difficult. In these mixed varieties (cellular-fibrinous) catarrhal pneumonic areas and fibrinous areas are found side by side in the same lung and even in the same lobe of the lung; in some infiltrated areas catarrhal and fibrinous masses are so intermingled that the composite picture shows neither the one nor the other form of pneumonia. Even microscopically the differentiation is difficult. In the sections prepared according to the method of Weigert, separate alveoli showed catarrhal inflammation (cellular exudate without or only with slight amount of fibrin) while other alveoli, near or even among these, were found to show the true character of croupous pneumonia. This then establishes a so-called "lobar-lobular" form of pneumonia, or, as Leichtenstern proposes to call it, a "cellular-fibrinous pneumonia," which he regards as characteristic of influenza.

Tetanus Due to Anti-Diphtheritic Serum.—The recent horrible deaths from tetanus, occurring in several persons who had been inoculated in Italy with anti-diphtheritic serum, seem to have been more exempt from condemnation than many other less important mistakes. Had only one patient been infected, it probably could have been attributed to a subsequent secondary infection, or to an accidental occurrence. But it is alleged that eight persons on whom the serum was used, died of tetanus, and that the serum was directly traceable to the Serotherapeutic Institute of Milan. There is as little excuse for such an outrageous sacrifice of human life as there is for permitting a rabid dog to run amuck. An institution that assumes the responsibility of manufacturing a substance which for curative or prophylactic purposes is to be injected into a living human body, ought to be possessed of sufficient skill

and common sense to test the serum before distributing it. The consequences are not only the shameful sacrifice of several human beings who might have been rescued from the ravages of diphtheria, but also the loss of confidence in the employment of serumtherapy. It is but a minor procedure to test serum before it is placed upon the market, and this is equally, if not more, important than testing the physiological action of well-known drugs. Italy has contributed much to medical science, and it is therefore more the pity that she has in this instance contributed such a medical martyrdom.

The Dangers of Specialism.—In certain obscure conditions it very largely depends upon the point of view from which the symptoms are studied as to what the ultimate decision and diagnosis will be. Thus, to the surgeon a persistent headache will suggest the possibility of specific new formations or growths of other origin, to the gynecologist some pelvic disturbance, and to the ophthalmologist a long-continuing eye-strain. Each is very prone to be biased by the line of work in which he happens to be engaged, and to look upon the given case only from the narrow beaten path of his daily routine. Just here lies one of the dangers, and possibly one of the greatest of the era of specialism into which we have been hurried by the rapid strides that have been made of recent years in the art of Medicine. The specialist must, to a certain extent, become a narrow man in a general sense in order to become at the same time an expert in a limited sense. Such is the paradox that confronts the medical man of the day. The passing of the general physician, as he was known a half century ago, and as was predicted 25 years ago, is now realized, or nearly so. It is rare indeed to find at the present time an all-around man with good judicial powers in all classes of cases, medical and surgical. The pathologist, lured by the winning mysteries of the autopsy-table, and fascinated by the revelations of the laboratory and microscope, finds no time to spend in the clinic or by the bedside, and neglects therapeutics proportionately as he cultivates the post-mortem. The busy physician, hastening from house to house and returning to find his anteroom filled with suffering humanity, is drawn irresistibly into the whirling vortex of symptomatology to the evident abandonment of the pathological table, save as the labors of his equally busy colleague in that department indicate to him a new and better line of therapeutics. The surgeon sees a surgical cause where the physician can advance an equally plausible explanation on medical grounds, and the physician too often presses his pathology beyond the borderline of surgical intervention.

Limited thus by his specialism and threatened at times to be carried beyond the line of sound reasoning by his enthusiasm, the practitioner of the twentieth century should pause to consider the adage of the

lamented Agnew: "A good physician," said he, "may make a good surgeon, but a good surgeon must be a good physician."

Here is the solution of the whole question. Specialism should be the result of a sound and natural growth, the result of an evolution brought about by a combination of circumstances and natural inclination. Beginning on the common ground of general practice, the young man should then drift, or better steer, in the direction which he finds most suited to his tastes and opportunities, thereby developing into a specialist with a good foundation of general medical knowledge, able to recognize causes foreign to his chosen territory and thereby opening to his patient the best prospect for early and proper treatment. Evil, indeed, must the consequences in most cases be of a deliberate choice of a specialty from the graduating day, with a corresponding neglect of everything else, and concentration of the faculties upon the chosen narrow line of work. Such a course is detrimental to the community at large and to the specialist himself, who thereby robs himself of additional ability and starves certain areas of brain-cells in order to overfeed others.

To a certain extent, it must be admitted, this rapid growth of specialism has been inevitable. The marked development of medicine and surgery along all lines, has made it impossible for the medical man to take a comprehensive view of every subject. It is not the specialism of necessity, however, that is objectionable, but that of deliberate choice without a preparatory course of general medicine that will afford a safe basis upon which the ultimate specialism should be erected.

Compulsory Vaccination in the Public Schools.—As the outgrowth of a case in which a child was excluded from the public schools of Philadelphia on account of failure to present a certificate or other evidence of successful vaccination—the position of the school authorities having been sustained by the Courts—a bill has been introduced into the Pennsylvania State Legislature for the repeal of the act making such evidence a prerequisite of the reception of school-children. We have so often in these columns dwelt upon the utility of vaccination in the prevention of smallpox, and the fact is so universally accepted by open minds, that we wish to refer to the circumstance only to suggest to our readers to use their influence with their representatives in the Legislature to prevent the possible repeal. A similar measure was defeated solely on its merits a year or two ago, and it is the duty of the medical profession to see that this new attack on preventive medicine suffers a like fate.

The Influence of Heredity.—This influence has, of course, always been appreciated, but probably never to the same degree or with the same critical intelligence as at present. The subject is of especial interest to the

physician by reason of its bearings upon disease and degeneration. It is true that disease itself is not transmitted by heredity, but rather a peculiar type of tissue, which renders the individual peculiarly susceptible to the influence of morbid agents. Disease in the fetus transmitted from the mother cannot be looked upon as inherited, but it is acquired in much the same way as disease is acquired in postuterine existence. In illustration of the influence of heredity in the development of the traits and qualities in the individual, Thomas Oliver (*Lancet*, November 10, 1900, p. 1335) points out that the Derby has never been won by a horse that was not a thoroughbred, and the same statement is practically true of the other great English races, the St. Leger and the Oaks. It appears, further, that the Derby has never been won by a gelding. Mares, also, have won races far less frequently than stallions. With the object of maintaining the high standard of the English race-horse, close breeding in and in is practised, and as a result of this practice, it is thought by many, the animal is degenerating. To overcome such a result infusion of fresh blood becomes necessary from time to time.

Anonymous Correspondents.—The man who writes anonymous letters is usually a libeller, and, as a rule, he is not worthy of notice. We feel constrained, however, to announce that we have received from such a correspondent a clipping, which he had cut from another journal, attributing to us the publication of a witless and indecent anecdote. It is, we trust, needless for us to say that this anecdote was never printed in this JOURNAL, but as it seems to be going the rounds among some of our contemporaries (who are entirely responsible for their own taste in the matter), we take this occasion to say that the anecdote not only never appeared in this JOURNAL, but that it would have been impossible for it to appear under either the former or the present editor. As our anonymous correspondent calls himself a "former constant reader" he could easily have verified this fact for himself, and is without excuse for not having done so.

Plague in India.—The plague in India seems to have attained unusual severity except in the central provinces. It is particularly severe in Bengal, where a weekly mortality of 2,500 is reported. The doctors being chiefly occupied in the famine district, there seems to be a lack of an adequate medical staff in the plague-infected portion of the country.

Appendicular Form of Pneumonia.—*La Semaine Médicale*, February 9, 1901, says that there is a form of croupous pneumonia which in its onset closely resembles appendicitis. Some 10 cases of this kind have been reported. The early symptoms are fever, repeated chills, pain in the right iliac fossa (over Mc Burney's point), sometimes bilious vomiting. After 2 or 3 days the pulmonary symptoms become manifest and then a typical case of croupous pneumonia follows. Operation has been indicated in some of these cases and a perfectly normal appendix found. It is remarked that the localization of the pain over Mc-Burney's point is not pathognomonic of appendicitis and that in all cases the lungs should be thoroughly and repeatedly examined. [T.L.C.]

Reviews.

The American Year-Book of Medicine and Surgery. Under the general editorial charge of GEORGE M. GOULD, M.D. Philadelphia and London: W. B. Saunders & Company, 1901. Price, \$3.75 per vol., net.

Dr. Gould's Year-Book has come to be a familiar publication to many busy doctors, and we doubt not that to all who take it the work is as useful as it is familiar. The editor and publishers announce that the issue for 1890, in two volumes, met with such general favor from the profession that they have decided to follow the same plan this year. Therefore, the work appears in two handsome, large volumes. Several advantages are gained by this plan of publication. The volumes are more easily handled, and, what is of the first importance, they are sold separately, as we understand it, so that the surgeon or the physician, as the case may be, need only buy the volume for which he has especial use.

We cannot attempt here to give a detailed review of a work which is itself essentially a review of all current medical literature. We are familiar, however, with the past volumes and have had frequent occasion to consult them, and have seldom, if ever, been disappointed in finding in them something that we needed. The present volumes have every appearance of sustaining the high repute of their predecessors. Such a work in its preparation must entail a vast amount of labor upon the editor and his collaborators, and they are to be congratulated and thanked also for having placed the profession under obligations for such a useful reference-book.

We notice that the volumes for this year are quite profusely illustrated, many of the illustrations being full-page half-tones. We doubt not that the work will continue to merit its popularity. [J.H.L.]

A Textbook of Histology, including Microscopic Technic. By A. A. BÖHM, M.D., and M. VON DAVIDOFF, M.D., of the Anatomical Institute in Munich. Edited, with extensive additions to both text and illustrations, by G. CARL HUBER, M.D., Junior Professor of Anatomy and Director of the Histological Laboratory, University of Michigan. Authorized translation from the second revised German edition, by HERBERT H. CUSHING, M.D., Demonstrator of Histology and Embryology, Jefferson Medical College, Philadelphia. With 351 illustrations. Philadelphia and London: W. B. Saunders & Co., 1900.

The announcement of an English version of a German work intuitively awakens expectation of something interesting and thorough.

In his preface the editor says that while in the main the original text has been retained, some changes in arrangement have been made. Further, that "additions to the German text have been freely made," the more important of these occurring in the chapters on Motor and Sensory Nerve-endings, on Spinal and Sympathetic Ganglia, on the Innervation of Glands and other organs, and in the chapters treating of organs with internal secretions. With this new text, that unquestionably is of great advantage to the book, many original and instructive illustrations have been incorporated. The author's preface is missing.

A considerable portion of the volume is devoted to microscopic technic; that of general application being treated in the first 50 pages, that of special application following each chapter of the general and "special" histology—not a novel plan but an excellent one, in which the authors follow other German works of this class. There is an eighteen page index, but this will not compensate the lack of cross-references. How, for example, is the practical person, who takes the work seriously, to find T. 85 referred to in the technic number 255, (page 273), or T. 144 in technic number 322, (page 434)? The pages on which T. 85 and T. 144 occur are not given; a serious omission in a book intended for use in the laboratory equally as in the study.

The usefulness to the student of this as of so many text-

books will in some measure depend on the teacher's selective faculty. It is brimful of interesting matter, descriptive and technical. [E.L.B.]

The American Illustrated Medical Dictionary. By W. A. NEWMAN DORLAND, A.M., M.D. Philadelphia & London: W. B. Saunders & Co., 1900. Price, \$5.00. Indexed.

Medical dictionaries grow old almost in the printer's hands, so great is the general advance along the lines of scientific medicine and so manifold are the terms employed. This work of Dr. Dorland is a highly commendable one, displaying painstaking industry and wide reading. The definitions are concise, and, as far as we have been able to determine, their brevity has not markedly injured their accuracy. The work is intended to stand between an exhaustive work, almost too verbose for every-day employment and the unsatisfactory pocket lexicon. In no medical work is typography so important as in a medical dictionary, and the publishers have every reason for congratulation in this respect. The plates are accurate and beautifully executed. In every case they enlighten the text, which is a desideratum not always found.

In a field so vast, it is scarcely comprehensible that error should not have crept in, or that certain definitions should not meet with criticism. For instance, the ophthalmologist will take exception to *exenteration* and *evisceration* being regarded as synonyms. And the hematologist will rise in his wrath to find under the definition of a *leukocyte*, "any colorless, amœboid cell-mass, etc.," whereas, it is known definitely that all leukocytes do not show amœboid movements.

The student will be particularly interested in the very exhaustive tables which are found. They include new anatomical, bacteriological, and eponymic tables of diseases, operations, signs and symptoms, stains, tests, etc. This feature of the work represents immense labor and judicious tabulation.

We cannot refrain from expressing ourselves most favorably upon the decidedly practical character of this work and its uniform excellence. [T.L.C.]

Flesh Foods, with Methods for Their Chemical, Microscopical, and Bacteriological Examination. A Practical Handbook for Medical Men, Analysts, Inspectors, and others. By C. AINSWORTH MITCHELL, B.A. (Oxon.), F.I.C., F.C.S. Small 8vo. Pages xvi, 322, and Index. London: Chas. Griffin & Co., Lim.; Philadelphia: J. B. Lippincott Co.

The author of this work has been for many years an active worker in food analysis. His editorial connection with *The Analyst* has given him a wide acquaintance with the current literature in this field. The work presents the results of these labors. The descriptions of analytic and bacteriologic methods are given in a practical form, a knowledge of general principles and technic in these lines being assumed.

The first 70 pages are devoted to descriptions of the structure and general nature of flesh, and the essential differences between the flesh of different classes of food-animals. A summary of the methods of testing follows, special attention being given to the processes for examining animal fats. It is interesting to note, in connection with one of these methods, that a marked improvement in detail, which saves several hours' work and which has been adopted by many chemists, is not noticed. This improvement was devised in the United States, and the omission of it by Mr. Mitchell is merely one of the many instances of the failure of English chemists to appreciate the work done in this country.

One chapter of 23 pages is devoted to the examination of sausages, which includes detailed methods for detecting horseflesh. Much space is occupied with the descriptions of the nature of proteids and proteid digestion. The last hundred pages cover the question of poisonous and infected food, all the important entozoa being described and figured.

The work is a useful contribution to an important department of practical hygiene and interesting evidence of the specializing tendencies of modern times. It is well written, well printed, and well illustrated. [H.L.]

Correspondence.

BILATERAL PAROTITIS AS A COMPLICATION OF
PNEUMONIA.

By AUGUSTUS A. ESHNER, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

OWING to the rarity of the association I desire to make brief record of a case of pneumonia complicated by bilateral parotitis. The patient was a woman, 71 years old, who was seized with pain at the base of the right chest, in which situation physical signs of pneumonia developed. Breathing was not greatly embarrassed, the temperature reached only a moderate elevation, and the pulse was not unduly accelerated. A crisis failed to occur at the expected time, but the patient appeared to be progressing satisfactorily. On or about the eighth day both parotid glands were markedly swollen and painful, and the temperature, which had been declining, had now risen again. Some relief was afforded by the application of ice, but the patient became gradually weaker and death took place 4 days later.

I am without a bacteriologic examination in this case, and cannot, therefore, say whether the pneumonia was due to the pneumonia-coccus or not, and whether the parotitis was a metastatic complication or merely an intercurrent affection. Bilateral parotitis, as mumps, is observed apparently as an independent affection, and parotitis, commonly unilateral, is occasionally observed as a complication of typhus and typhoid fever, as well as other infective processes. The question thus naturally arises whether there is a specific variety of parotitis (bilateral mumps) dependent upon an as yet undiscovered microorganism, or whether unilateral or bilateral parotitis may be due to any one of a number of microorganisms—the typhoid bacillus, the pneumonia coccus, etc.

A CASE OF ILLUMINATING GAS-POISONING.

By WM. A. STEEL, M.D.,

of Philadelphia.

Resident Physician, Hospital of the P. E. Church.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

At the request of my "Chief," Dr. Henry M. Fisher, I report the following case of illuminating gas-poisoning:

At 11.45 P.M., January 13, Cecelia B—, 8 years old, was carried into the Episcopal Hospital in an asphyxiated condition from inhalation of illuminating gas. There was a white froth at the mouth, the skin was clammy and livid, the muscles were in general tonic spasm, the patient lying in a position of opisthotonos; eyes rolled up with slight external squint, respirations jerky and intermittent, radial pulse, not countable. Atropin was given hypodermatically and oxygen administered for two hours, at the end of which time respirations were freer, the pulse could be counted at 180; hands, feet and face still cyanosed. Patient was then put in hot packs, free sweating resulted, muscular spasm relaxed, radial pulse fell to 160, rectal temperature 102.3°. She became quiet and seemed to fall into a natural sleep, although consciousness was not regained.

At 3.00 A.M. the rectal temperature was 106.3°; at 5.00 A.M., 107.2°; at 7.00 A.M., the mercury filled the entire thermometer tube at 110°. The respirations were again jerky, radial pulse uncountable, heart-beats 215 per minute. Patient was given a cold plunge and free stimulation hypo-

dermatically, followed by hypodermoclysis (1 pint of normal salt-solution) in the buttocks. Oxygen was administered for one hour, and for 15 minutes during each following hour, temperature dropped, after plunge to 103.4°. Free enuresis and sweating followed hypodermoclysis and bath.

Patient became conscious 6 hours later, and in fair physical condition, with exception of tonic contraction of all the muscles of the right arm. The arm could be extended, giving some pain to the child, and at once flew back to its flexed condition when the extending force was removed. There was no pain on pressure over the nerve-trunks. The muscles gradually relaxed, the arm assuming its natural condition and function within 48 hours.

The urine voided 8 to 10 hours after the accident threw down a heavy sediment of large uric acid crystals, otherwise it was negative.

Child was discharged well the fifth day after the accident.

A CORRECTION.

By G. E. DE SCHWEINITZ, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In the report of the meeting of the Neurological Society on January 28, published on page 196 of the PHILADELPHIA MEDICAL JOURNAL for February 2, 1901, referring to the ophthalmoscopic appearances associated with brain tumor, occurs the following sentence attributed to me: "The star-shaped figure seen in the macula is of importance in that it also occurs in Bright's disease and in syphilitic retinitis, hence it is not pathognomonic of brain tumor." This sentence should read: "The star-shaped figure seen in the macula in albuminuric retinitis and usually supposed to be pathognomonic of Bright's disease, especially of the interstitial variety, occurs also in choked disc, recurring hemorrhages in the retina and vitreous in young individuals, and sometimes in cases of syphilitic neuro-retinitis."

Essay on Thirst: Its Causes and Mechanism.—

André Mayer (*Gaz. Heb. de Méd. et de Chirur.*, December 30, 1900, 47me Année, No. 104; Paris Thesis, 1899-1900, No. 565) has first studied the role of water in the organism, and shows that although it serves mechanically for the construction of the cells, its principal role is as a universal dissolving agent. He has demonstrated, both within and without the cells, the existence of solutions of organic matters and of salts. These solutions ought to obey the physical laws of solutions in general. The author goes on to show that within the body there are variations of the osmotic tension of the humors, and that the causes that produce them are precisely those that produce thirst. In other words, thirst is due to the increase of the osmotic tension of the internal media. This increase of tension brings a mechanism of vascular regulation to bear on all the organs that have as their function the restoration of the normal osmotic tension when that tension is disordered. This automatic mechanism produces as a last manifestation the appearance of a physiologic phenomenon that is the organic basis of the sensation of thirst. The nervous center that controls this sensation is situated in the medulla. Whether or not a cerebral center exists, the author is not able at present to locate it. Studying thirst in man, Mayer divides the concomitant phenomena into 2 successive periods: The first, a tonic period, during which there is a sensory erethism; the second, a period of depression, corresponding to the period in which the osmotic tension is augmented in the entire circulatory system, and during which there is a sensory depression. The author then studies the psychologic aspect of his subject, and shows us that in individuals attacked with morbid thirst there is psychologic trouble of conscience, during which pathologic impulses frequently present themselves. [J.M.S.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA.

Milk Inspection.—W. J. Byrnes, Chief Milk Inspector, reported that during January 4272 inspections of samples of milk were made, and a total of 83,855 quarts examined. Of this number 1486 quarts were condemned.

Dr. Henry S. Mellinger, one of the best known physicians in Lancaster County, died at his home on February 7 at Creswell, aged 79 years, from apoplexy. He graduated from Jefferson Medical College, Philadelphia, in 1845.

Physicians Meet at Newtown.—For the first time in 50 years, a meeting of the Bucks County Medical Society was held at Newtown on February 7. The society decided to hold its winter meeting at this place yearly hereafter. Prof. James Tyson, of the University of Pennsylvania, was the speaker.

Philadelphia Neurological Society.—The following officers were elected for the ensuing year: President, Dr. James Tyson; vice-presidents, Drs. C. S. Potts and F. X. Dercum; secretary, Dr. A. A. Eshner; treasurer, Dr. G. Hinsdale; councillors, Drs. D. J. McCarthy, J. Sailer, and W. G. Spiller.

Druggist Censured.—The coroner's jury of Philadelphia recently rebuked a Philadelphia druggist for selling poison to a minor without any prescription and recommends that an act of Assembly be passed by the Legislature restricting the sale of poisons and medicine containing poisons. Such legislation would undoubtedly be of great advantage to the community.

Dr. Benjamin Franklin, a native of New York, died February 6, of the grip at his home in Newark, N. J., where he had practised medicine for 25 years. Dr. Franklin was a veteran of the Civil War, and was a prisoner for 7 months at Andersonville. He also served with the Cuban patriot army in the 10 years' war in Cuba. Dr. Franklin was 54 years of age, and a graduate of the University of New York.

Children's Hospital.—After a lively meeting of the Board of Managers, a new staff consisting of homeopaths is expected to be in full charge of the medical portion of the institution. There having been no regular medical staff for some months, a number of influential physicians in Germantown and other portions of the city were invited to act on the staff. The president decided with the consent of a majority of the board to change the institution from allopathy to homeopathy, whereupon some of the members of the board resigned.

College of Physicians.—At the stated meeting held February 6, Dr. J. CHALMERS DAcOSTA read a memorial of the late Sir James Paget, who was an honorary member of the college. The address was a fitting and eloquent tribute to the memory of one who was great not only as a surgeon but as an unassuming and conscientious man.

DRS. JAY SCHAMBERG and J. FRANK WALLIS exhibited wax models illustrating various cutaneous diseases and gave a detailed description of their construction.

DR. B. ALEXANDER RANDALL read Notes on fifty cases of otitic extradural abscess. The histories of several cases were detailed. The point emphasized was that in acute as well as chronic otitis collections of intracranial pus may be present with but few symptoms referred to that location. In only one or two instances has he found involvement of the eyeground. In these cases the antrum should be freely opened to give access to the pus cavity. As a rule these abscesses are harmless when they are properly evacuated.

DR. J. B. ROBERTS exhibited a cast and skiagraphs of a case of so-called Smith's fracture of the radius and a skiagraph of a case of so-called Bennett's fracture of the metacarpal bone of the thumb or stove of the thumb. The cast and skiagraphs came from Dublin and have been donated by Dr. Roberts to the Mütter Museum.

DR. H. R. WHARTON reported for Dr. J. H. MUSSER and him-

self a case of perforated gastric ulcer; operation; recovery. The patient was a man of 48 who had had gastric disturbance and pain for 3 or 4 months but had not vomited blood. Six hours after the onset of sudden epigastric pain which caused the man to faint the abdomen was opened. A perforating ulcer was found on the posterior surface of the pyloric end of the stomach about one-half inch from the duodenum. The edges of the opening were very friable, the opening being finally closed by infolding it by means of six silk sutures inserted at some distance from the edge. The abdomen was flushed with 6 gallons of hot saline solution and two glass drainage tubes inserted. Recovery was uneventful. Dr. Wharton believes thorough irrigation is the best procedure in these cases. Pelvic drainage should be obtained by means of a long drainage tube or by a counter-opening.

Vital Statistics of Philadelphia for the week ended February 9, 1901:

Total mortality	549
CASES.	DEATHS.
Inflammation of appendix 1, bladder 3, brain 11, bronchi 13, heart 1, kidneys 21, larynx 3, lungs 115, pericardium 2, peritoneum 10, stomach and bowels 15, spine 1	196
Inanition 12, marasmus 10, debility 6	28
Tuberculosis of lungs	77
Apoplexy 18, paralysis 5	23
Heart—diseases of 24, fatty degeneration of 4, neuralgia 3	31
Uremia 9, diabetes 4, Bright's disease 9	22
Carcinoma of breast 3, stomach 6, uterus 2, tongue 1	12
Convulsions	15
Diphtheria	95
Brain—softening of 1, disease of 1	2
Typhoid fever	36
Old age	17
Burns and scalds	2
Suicide	2
Cirrhosis of liver	4
Alcoholism	1
Cyanosis	4
Gangrene of foot	1
Scarlet fever	83
Abscess of arm 1, of ovaries 1, abortion 1, asthma 1, aneurysm of aorta 1, casualties 6, congestion of lungs 10, childbirth 1, membranous croup 2, epilepsy 1, erysipelas 3, gallstones 1, hemorrhage from stomach 2, from uterus 2, umbilical hemorrhage 1, influenza 28, intussusception of bowels 1, jaundice 1, locomotor ataxia 1, necrosis of bone 1, obstruction of the bowels 1, edema of glottis 1, purpura hemorrhagica 1, pyemia 3, rheumatism 2, arterial sclerosis 1, spine 1, surgical shock 1, sore mouth 1, stricture of esophagus 1, suffocation 2, tetanus 1, brain tumor 1, whooping-cough 3	86

Physicians Elect Officers.—The Atlantic City Medical Society held its annual meeting at Atlantic City February 6, and elected Dr. Theodore Boysen, of Egg Harbor City, president. The other officers are residents of Atlantic City, and are as follows: Dr. W. K. Darnall, vice-president; Dr. Theodore Senseman, secretary and treasurer; Dr. A. B. Shimer, reporter.

Pediatric Society.—At the meeting of February 12, Dr. J. D. TARGET exhibited a case of Jacksonian epilepsy in a girl of 7 years. Convulsive movements began in the left leg, which is now partially paralyzed, and have now extended to the arm. The parents refuse operation.

DR. J. P. CROZER GRIFFITH exhibited: 1. A case of splenomegaly, with enlarged liver. The child is 10 months of age, the spleen and liver being greatly enlarged. An important point is that there is no decided evidence of rickets in the case. Dr. Griffith has seen several cases of enlarged spleen without evidence of rickets and knows of no reason why such cases should not be classed as splenic anemia. 2. A case of probable peritonitis in a colored girl of 8 years. 3. A case of congenital cyanosis. The infant becomes much more blue when crying. No distinct heart-murmurs are to be heard, but there is accentuation of the pulmonary second sound. For these reasons there is believed to be an abnormal origin or a transposition of some of the bloodvessels.

DR. JOFSON exhibited a case of nodding spasm in which there is also slight nystagmus and some contraction

of the left sternomastoid muscle. There are no well-marked symptoms of rickets.

DR. D. L. EDSELL reported a case of **gumma of the liver** in a child of 14 years. The child was deaf in both ears, had ozena, and an old keratitis, the liver was enlarged and nodular and there were effusions into the serous cavities. Inunctions of mercury and the use of the iodids soon caused an improvement and finally a cure, so far as can be determined, the liver becoming normal in size and the effusions disappearing. Kidney involvement, as evidenced by albuminuria, also cleared up. The great frequency of mistakes in diagnosis was noted, the condition very often being diagnosed as malignant, even by prominent clinicians.

DR. J. P. CROZER GRIFFITH detailed a convenient plan for **bedside case-history taking in private practice**. After trying several plans, one which has given satisfaction for nearly 2 years, is that of a pocket-case with 2 large pockets for cards. Card histories from the office can thus be taken to houses when office patients are visited. Slips on which to write directions for diet, medicine, etc., as well as printed slips giving directions for making barley water, beef juice, etc., and preparing baths, are also carried in the case.

DR. EMERY MARVEL reported a case of **suppurating mastitis in the newborn**. The infant was 27 days old. The abscess, which was incised and evacuated, is believed to have been due to irritation from within by a hypersecretion of colostrum. In such cases prophylaxis may be of use if the condition is recognized early.

DR. T. S. WESTCOTT read **A note on the differential modification of the proteids of milk**. Formulae were given based upon a ratio of 4 to 1 between caseinogen and whey proteids. This ratio is believed to be more correct than the former used—5 to 1. The change is based on recent reports, especially that of Drs. White and Ladd in the PHILADELPHIA MEDICAL JOURNAL of February 2.

Obstetrical Society.—At the meeting of February 7, DR. WILMER KRUSEN read a paper on **Organotherapy in gynecology**. The literature of the subject was carefully reviewed, including the use of uterine, mammary, parotid, thyroid, and ovarian extracts. Of these the thyroid is the most efficient and has been most thoroughly tried. Dr. Krusen has been prescribing ovarian extract for 3 years for 2 classes of cases: 1. In amenorrhea and dysmenorrhea. 2. For symptoms following the removal of the uterine appendages. 3. For disturbances due to the natural menopause. Most cases are disappointing, but an occasional success incites to renewed use. The best results are noticed in the second class of cases, the congestive and nervous symptoms being ameliorated in some instances. No definite and exact reliance can be placed on the drug. In discussing the paper, DR. SHOBER said that the chief indication for the use of mammary gland was in uncomplicated cases of bleeding fibroids. It would not cure the condition but would control the hemorrhage and thus put the patient in better condition for operation. He is also convinced that parotid extract will control ovarian pain in patients who have enlarged, prolapsed, and tender ovaries without adhesions.

DR. H. A. HARE stated that he would speak from a theoretical rather than a practical standpoint. An important point is to know the relative activity of the gland which is being prescribed. A knowledge of the condition of the animal from which the gland was obtained is necessary to get definite conclusions. Many contradictory reports may have thus arisen. Again, the minute metabolism of each patient is not known, and thus the exact cause of the condition may be different in different individuals and be acted on differently by the extract given. The fact that some observers report such gratifying results rather militates against the use of extracts as this is comparable to drugs which give wonderful results in the hands of some one individual but which are considered of no value by the profession at large. Because different organs are similarly involved, as the parotid gland and the ovary in mumps, does not prove them to have a physiological connection. They may be only bacteriologically similar. The connection between the ovaries and the mammary glands may be only a reflex one. Physicians will not be able to employ organotherapy in a rational way until they are able to separate symptoms and locate more definitely their cause in individual cases. DR. J. M. BALDY practically agreed with Dr. Hare's conclusions. The application of

these remedies is very limited, although thyroid extract has aided in controlling hemorrhage in a few instances, in nulliparous women only. It has been of use in several cases of irregular menstruation. DR. W. W. RUSSELL, of Johns Hopkins Hospital, stated that organotherapy had been practically useless in his experience. The use of suprarenal extract locally gave a gratifying result in one case. The patient had been treated unsuccessfully for 9 months for bleeding from one kidney. Through a catheter $\frac{1}{2}$ ounce of a 10% solution of suprarenal extract was introduced. There has been no return of the bleeding for 3 months. DR. E. E. MONTGOMERY finds that thyroid extract may cause a recurrence of pregnancy in obese women. He believes the involvement of the parotid gland following operation to be the result of infection rather than from a physiological connection. In the irregular bleeding of women who are near the climacteric, thyroid extract has a certain use. It also moderates the severe pain in malignant disease. DR. J. G. CLARK has been prescribing parotid extract systematically for 3 or 4 months in cases of dysmenorrhea with not the slightest result. DR. J. M. FISHER stated that the use of thyroid extract at the Jefferson Clinic reduced the weight of patients and was serviceable in some cases of amenorrhea. Ovarian extract gave no results. In private practice one case had improved by its use. DR. J. C. DACOSTA confines the use of thyroid to cases of fibroid who refuse operation. Most cases are reduced in size and the hemorrhage ceases. The decrease in size is apt to be temporary.

DR. E. E. MONTGOMERY read a paper on **Operative treatment for cancer of the uterus**. The condition of the patient should determine whether the vaginal or abdominal method should be used in the radical treatment. The vaginal method should be used in cases where the disease is confined to the cervix; the uterus is freely movable, and the vagina is roomy. The excision must be made in healthy tissue and reimplantation prevented by a preliminary curettement and suturing of the cervix. In abdominal hysterectomy the pelvic glands are not to be removed as a routine procedure; the glands are rarely involved in operable cases; the prognosis is unfavorable in patients under 35. DR. J. G. CLARK makes the removal of the glands dependent on the condition of the patient. If, after removing the broad ligaments and getting the ureters well out of the way, the patient is in fair condition, he removes the glands. If the patient's condition is not good, the operation is stopped. The removal of the glands is of prognostic value. If they are found by microscopic study to be involved, the prognosis is very unfavorable. He supports Freund's views in regard to the route selected—vaginal, if the condition is incurable; abdominal, if there is hope of cure. DR. J. M. BALDY stated that cancer of the fundus and of the cervix were practically two diseases, so far as prognosis is concerned. The majority of the former get well, the latter all die. The statistics of the German writers are not to be relied upon. The attempt to clear out all the glands will lose cases. Beside this, it is impossible for any man to dissect out all the glands of the pelvis. Pathologists disagree regarding the condition present in many of these cases, hence the clinician must not depend too much upon their dictum and seek to remove too much tissue. Owing to the lateness of the hour, DR. GEO. ERETY SHOEMAKER merely mentioned several cases he had to report.

NEW YORK.

Dr. John J. McGrath has been appointed attending surgeon to the Harlem Hospital.

State Medical Society.—The following officers were elected January 31, 1901: President, Dr. Henry M. Elsner, of Syracuse; vice-president, Dr. Louis M. Lanehart, of Hempstead; secretary, Dr. F. C. Curtis, of Albany; treasurer, Dr. C. D. Ball, of Albany.

Report of the New York Orthopedic Dispensary and Hospital.—During the year ending September 30, 1900, 164 patients have been admitted to the wards of the hospital, 110 discharged improved, 3 unimproved, 3 died and 48 remained under treatment October 1, 1900. The number of days of hospital care for free patients was 17,902; for pay patients, 2394; total, 20,796. Thirty-six patients were treated by operative measures, and 57 operations were performed.

All were successful. The out-visiting nurse has made 2265 visits to the homes of patients discharged from the hospital.

Neurological Society on Insanity Law.—At a meeting of the New York Neurological Society, held in the Academy of Medicine, resolutions were adopted in regard to the qualifications required for the President of the State Commission on Lunacy. Bills relating to this subject and providing also for a change in the State insanity measures are at present before the Legislature. The resolutions condemn any amendment of the State insanity provisions which do away with the clause providing that the medical member of the commission shall have had five years' actual experience in the care and treatment of the insane.

Medical Profession Honor Prof. Francis J. Quinlan, M.D., LL.D.—A large number of physicians of New York City tendered to Prof. Francis J. Quinlan a complimentary dinner, and a magnificent loving cup beautifully inscribed. They gathered to give testimony of their recognition of the esteem and appreciation in which they held their honored guest not only as a physician, but as a citizen. Speeches were made by Professors Wythe, Townsend, Robinson, and T. A. Emmett. Drs. Phelps McGuire and Smith represented St. Vincent's Hospital; Dr. John McGarth, the Postgraduate School; Dr. Joseph Bissell, Bellevue Hospital, New York City; Dr. Aspell, the Cornell Medical College; Drs. Bodine and Doherty, the New York Polyclinic; Dr. Thomas Manley, the Harlem Hospital; Dr. Quigley, the Fordham Hospital; Dr. P. V. Burnett, the Brooklyn Eye and Ear Hospital; Drs. Ledermann, Hepburn, and MacDonald, the Manhattan Eye and Ear Hospital; Drs. Callan and McCoy, the New York Eye and Ear Infirmary, whilst Dr. Dalrymple came from New Rochelle to add to the occasion. Dr. Nevin journeyed from Jersey City, and Dr. Morris Manges ably represented Mount Sinai Hospital. Many other prominent doctors were seen at the different tables, and the evening was one long to be remembered by all present.

New York Academy of Medicine—Section on Orthopedic Surgery.—Meeting of January 18, 1901. Dr. George R. Elliott, chairman.

Dr. HOMER GIBNEY presented a girl, aged 17 years, tall, with a round back or posterior curve of adolescence, of which he exhibited a tracing. He had applied the plaster jacket she now wore, only a few hours before, by placing her in the recumbent position, the body resting upon two up-rights—one under the pelvis, and the other under the point of greatest prominence of the back. Her head and shoulders were allowed to sag backwards and downwards. The position maintained, which caused the patient some suffering, was a marked overcorrection. Another jacket would be applied later. The patient did not bear the operation well on account of cardiac complication. Dr. HENRY LING TAYLOR said he had not understood what diagnosis had been made, but the girl seemed unusually tall for the age assigned, and asked if the possibility of gigantism had been considered, as a marked round back was common in such conditions. Dr. ROYAL WHITMAN said he was familiar with the history of the patient. She had some cardiac disease, was rickety, overgrown, and badly nourished. He considered her condition merely the round spine of adolescence, partly due to her height and heart-weakness, and called attention to the patient, showing lack of ordinary intelligence. Dr. GEORGE R. ELLIOTT asked Dr. Gibney how much force in pounds he had used to correct the deformity. Dr. GIBNEY replied: that little force beyond gravity was used, the sagging of the body between the supports appeared to give the necessary extension. Dr. W. R. TOWNSEND said that he had put up a case of spondylose rhizomelique last week in a much straightened position, followed by a feeling of relief to the patient. Dr. TAYLOR remarked that Kietely had described anterior crutches to hold the shoulders back, which would seem to answer the purpose of epaulettes as used in this jacket, without their disadvantages.

Epicondylar Fracture of the Elbow.—Dr. HOMER GIBNEY presented a small boy who had sustained a fracture of the elbow three months previously. The fracture was above the condyle. When the patient presented himself at the hospital the elbow was fixed at an angle of 105° with but little movement. The joint was cut down upon by Dr. V. P. Gibney and the detached fragment sutured into place.

Dr. V. P. Gibney said the epicondyle and nearly the entire condyle had been displaced, interfering with motion. He had cut down upon the joint and separated it with an osteotome, cleaned off the site of the fragment and pushed it down, suturing with kangaroo tendon; he then put the arm in a straight position, left it for four or five weeks and then allowed active motion. Passive motion was not employed. Dr. T. HALSTED MEYERS commented upon the excellent result and remarked that children were often allowed to go on with fracture at the elbow united in poor position in the belief that they would outgrow the disability in great degree, which was true, but it was better to correct the deformity entirely, even resorting to open operation when necessary. He called attention to Dr. Lloyd's excellent reports.

Coxa Vara.—Dr. TOWNSEND presented a boy, aged 14, with the history that three years ago, without apparent cause, began to limp and noticed that one leg was a little shorter than the other. The condition increased and he has had some pain. There was one inch of actual shortening. Radiographs were shown. He diagnosed coxa vara of the ordinary type. He said there were two points to note: One, good flexion and extension with little adduction; the other, the smaller size of the limb. Dr. Townsend showed another skiagraph of a patient in which he had made the diagnosis some time ago of coxa vara. In this case, under observation for three years, there had been a progressive shortening of about $\frac{1}{2}$ to $\frac{1}{4}$ inch each year, now amounting to $\frac{3}{4}$ of an inch. Dr. WHITMAN called attention to the importance of the limitation of motion, that although the patient still retained 10% of abduction, there was an apparent shortening of two inches. This shortening and consequent disability was due to the limitation of abduction. This deformity might be overcome, after preliminary stretching of the contracting muscles, by a cuneiform osteotomy at the base of the trochanter which would reestablish the angle of the neck and thus relieve the strain upon it. He advised this operation in Dr. Townsend's patient, though the best results were to be looked for in younger patients, or at an earlier stage of the deformity. Dr. ELLIOTT asked Dr. Whitman how large a wedge of bone he would remove. Dr. WHITMAN suggested cutting a paper model of the bone as shown in the skiagraph, and measuring on that the size of wedge to be cut out; he thought one with a base of $\frac{1}{2}$ of one inch would be sufficient in the patient under discussion. Dr. ELLIOTT asked if the length of the limb would be much increased. Dr. WHITMAN replied that the actual increase in length would be slight, possibly $\frac{1}{2}$ inch; the important point was that there would be no apparent shortening because there would be complete relief of the limitation of motion which caused the apparent shortening. Dr. TOWNSEND said, he had performed the operation referred to by Dr. Whitman in two cases with good results and saw no reason why it should not be done in this case. In one patient, however, a little girl, aged 7 years, who had slight coxa vara, he had applied a traction splint and did not see in this particular case why it was not as good as the osteotomy advised by Dr. Whitman. He thought apparatus worn for a few years would give good results in the mild cases. Dr. MEYERS agreed with Dr. Townsend that it would be better in the beginning of these cases to use some sort of supporting apparatus that would not need bandage or plaster, thus avoiding pressure atrophy. He thought the Campbell brace especially adapted for such cases. It removed part or all of the body weight and was inconspicuous. Dr. V. P. GIBNEY asked just what the Campbell brace was. Dr. MEYERS illustrated it by a drawing showing it extending to the hip. Dr. GIBNEY asked if the Campbell brace had always extended to the hip as drawn by Dr. Meyers. Dr. MEYERS said that it had for the last 18 years. Dr. TAYLOR said that this brace reminded him of the Dow's brace which was valuable when it was desirable to use a perineal crutch and allow motion at the knee. He cited cases which had done well under the use of the hip-splint, but could not give final results as the patients had not returned after treatment was discontinued. He had recently seen a case of coxa vara in consultation when 4 out of 6 surgeons consulted were in favor of the splint treatment. Dr. WHITMAN did not favor the use of apparatus as a routine treatment, believing that after its discontinuance the distortion was likely to increase. The nutrition of the parts was likely to be lessened rather than increased by the use of braces. He had been disappointed in the final effect in cases

in which apparatus had been used. Finally, braces could not rectify the deformity, at best it would but relieve the symptoms and check progress. His operative results had been satisfactory. The patients after operation did not limp. Nearly all of his operative cases were between the ages of 6 and 10 years. DR. TOWNSEND asked if the boy in question would walk perfectly if the adduction were overcome. DR. WHITMAN said if there was no limitation of abduction, the boy would walk almost perfectly; whatever limp persisted would depend upon the actual shortening. DR. ELLIOTT wished to know what would be the prognosis if the case was left untreated. DR. WHITMAN replied that the patient would not get much worse, might get some better; as a rule, after the more acute symptoms had subsided the patients adapted themselves to the deformity and got along very well with a greater or less degree of limping. He stated that several of the German writers were apparently opposed to either mechanical or operative treatment. DR. LOUIS A. WEIGEL, of Rochester, N. Y., thought apparatus might be used to advantage in the earlier stages of coxa vara for the removal of superincumbent weight which is an etiologic factor. He believed the difference in size of the femora as shown in the radiographs was due to a true atrophy or arrest of development. If coxa vara is due to defective nutrition, development of the affected side would be retarded.

Fracture of the Neck of the Femur.—DR. TOWNSEND presented a man, 19 years of age, who in December, 1899, fell a distance of 40 feet, striking on his hip. A diagnosis of contusion was made at the hospital to which he was taken, where he remained in bed 6 weeks, at end of which time he could not walk, except with the aid of crutches. He came to the Hospital of Ruptured and Crippled in April, 1900, and a diagnosis of fracture of the neck of the femur was made. There was one inch of shortening, inversion of foot, crepitation at site of fracture when movements were made. Extreme pain and inability to bear weight on the limb or lift it from the table when lying on his back. A long, traction hip brace and a high shoe were applied and worn for 6 months. The man can now walk with little or no pain, and when lying on his back can raise his leg nearly as well as on the sound side. There is one inch of shortening, no crepitation at hip, and all motions are possible without pain. Dr. Townsend thought traumatic coxa vara could be applied to this case. DR. MEYERS thought the case very encouraging. He had presented a similar case some time ago, where bony union had been secured after 4 months of nonunion. In all cases of fracture of the neck of the femur, an earnest attempt to get bony union should be made. In recent cases, even in old people, with proper splints we would succeed many times. In old people where there had been fracture without real immobilization for many months, the case was not hopeless under proper treatment. DR. WEIGEL exhibited a radiograph of an unusual deformity of the tibia and fibula, following a probable fracture during infancy. The mother had noticed a slight angle, middle $\frac{1}{3}$ of tibia when child was 3 months old. This had increased. The original fracture may have occurred in utero. Dr. Weigel also presented a series of radiographs, showing congenital absence of bones in members of the same family. In the 5 extremities shown, some bone of the hand or arm was absent. In one case there was a rudimentary humerus, an imperfect thumb, and 3 fingers. The mother had no thumb, and gave a history of having born 12 children, four of whom were deformed. The mother attributed her own deficiency to maternal impression, stating that her mother, while pregnant, was shocked by seeing a man at her house without a thumb. Dr. Weigel exhibited another radiograph of a case of extensive osteomyelitis involving the whole of the tibia on one side. The patient had been treated for articular rheumatism. He thought it possible in most cases to make the differential diagnosis between marked suppuration and thickening or eburnation. When there is pus formation, he states that in a radiograph it is difficult to get a clear definition of bone structure on account of the osteoporotic condition usually present. Dr. Weigel also exhibited a radiograph of a tubercular focus in a child's foot, together with another radiograph taken 2 months later, showing the reparative process already well under way. This patient was treated by fixation and rest, any radical surgical interference being contra-indicated. DR. TOWNSEND asked for a differential diagnosis between sarcoma of bone and osteomyelitis. DR. WEIGEL

said that such a differential x-ray diagnosis might be difficult to make without an opportunity of comparing a series of cases. DR. ELLIOTT showed a skiagraph of congenital dislocation of the hip, which was taken after only 15 seconds of exposure. The shortness of time exposure was important. With restless children, long exposure was often impossible without an anesthetic.

Transactions of the New York Obstetrical Society.—Stated meeting, held Tuesday, January 8, 1901. President Dr. H. J. Boldt in the chair.

DR. JANVRIN presented a specimen of **large myomatous growth of the uterus**. The history was as follows: Patient single, 40 years of age, menstrual history regular, no pain or bleeding. One month ago she had her normal period, which continued for several days, after which she began to flow freely. The hemorrhage was controlled somewhat, but she continued to flow for several weeks. Upon examination at the end of 3 weeks, a large abdominal growth was found and the tumor removed, which is here presented. Several cysts of the ovaries were removed at the same time. The case was of interest because no hemorrhage had occurred until the last month, although the mass was of large size. The reason for this lies in the fact that the tumor is probably of the cystic variety.

DR. BOLDT presented a specimen of **tubal pregnancy**, in which the fetus of 2 months was found still within the tube. The great interest in this case lies in the fact that operation was performed as the process of tubal abortion was taking place. The abdominal extremity of the tube is dilated to a diameter of 1 cm. The uterine end is completely occluded. The tube is $2\frac{1}{2}$ cm. in diameter at the thickest point. The patient had been bleeding for 3 months at irregular intervals, accompanied by cramp-like pains. During the week before operation the bleeding was very profuse, so that the physician (who thought that the patient had an intrauterine pregnancy) said that she would abort. Large clots were expelled per vaginam. The patient was very anemic, and suffered great pain. In the abdomen there was a large quantity of blood which had escaped at different times, shown by the varying degrees of consistency; some clots were recent, bleeding continuing from the tube, while some were very firm and yellowish-red, the latter being on the floor of the pelvis. The bleeding for such length of time without completion of the abortion is the main interesting feature.

DR. VINEBERG said that the case was of great interest, showing as it did, that we may get as profuse a hemorrhage from the uterus in ectopic gestation as from an intrauterine abortion. He also emphasized the advisability of anesthetizing in cases of supposed abortion in order to make a careful diagnosis of the exact conditions. DR. BROTHERS mentioned the fact that some men thought it unnecessary in cases of tubal abortion to perform laparotomy, or to excise the tube. But in cases like this one of Dr. Boldt's, where the diagnosis of tubal abortion is made and where the patient may lose her life from exsanguination, the loss of blood occurring externally or in the peritoneum, one is justified in doing an abdominal section and removing the diseased tube. DR. JANVRIN remarked that in many cases upon which surgeons are called to operate there is really a tubal abortion present and no rupture of the tube itself. It is rare for hemorrhages to continue from a tube for 2 or 3 weeks without abortion being complete. In most cases tubal abortion takes place inside of a week. In his opinion there was no question of the necessity for operation in any case where hemorrhage was going on. DR. BOLDT in closing said he believed that an impregnated tube should be treated as one of malignant disease and operation was therefore indicated.

DR. H. J. BOLDT read the paper of the evening. The subject was: **1. The Definition of septicemia and pyemia; 2. The indication for vaginal hysterectomy and for abdominal section and drainage in puerperal fever.** The writer in reviewing the bacteriology of the ailments under discussion, said that while there were many varieties of streptococci, they could be divided into three classes or varieties, depending upon their virulence. In order to show the various definitions for septicemia and pyemia and their mingling with the terms septic infection and septic intoxication, thus creating confusion, the author quoted from a number of recent textbooks and dictionaries. So different in meaning are these various

definitions, that one is necessarily confused in choosing the correct term for a given pathological condition.

The best definition for septicemia is given by Coplin in his "Manual of Pathology," third edition, published in 1900. This is found on page 389, under the term "Mycoses of the Blood." He states that "in these the bacteria are present and multiplying in the circulating blood in which their products are generated. The intensity of the septic phenomena is augmented by the greater production of the poison, and not having even the barrier of protection afforded by the necessity of osmosis or absorption, they are enabled to engender lesions not presumed to occur, at least not to the same extent, in either sapremia or local infection. The embolic production of abscess is the essential element of pyemia, a disease recognized by surgeons as septicemia, plus the infected emboli, to which are attributed metastatic abscesses."

Delafield and Prudden, in their "Pathological Anatomy and Histology," fifth edition, state that "If from a focus of suppurative inflammation due to microscopic organisms, or if from a point of entrance of microscopic organisms without local reaction, the germs and their product become distributed through the body, inducing disease, the general condition is called septicemia. If in the invasion of the body by the microscopic organisms and their products new supplementary foci be established, it is now customary to designate the condition pyemia."

Dr. Boldt in his paper makes use of and favors the terms "acute" and "chronic" bacteremia. He defines "acute bacteremia" as a blood disease caused by microscopic organisms invading the circulation from some primary seat of infection. These infection-producing elements multiplying so rapidly in the blood that the patient usually succumbs within 5 days after the disease begins. Usually the parasitic germs are streptococci pyogenes, but other pathological germs may be present also. Chronic bacteremia (or pyemia) is likewise caused by the invasion of the system by microscopic organisms, but they disseminate from an infected thrombus. They are not diffused into the system in large quantity, neither are they possessed with the same foudroyant virulence from a clinical standpoint. The production of the abscesses found in the condition called pyemia, and upon which the pathological difference between the two conditions depend, is due to the parasitic organisms finding a resting place outside of the blood circulation, and there giving rise to abscess formation. That there is a decided difference in the virulence of streptococci no one will deny; for instance, an incised wound of the finger may be infected with pus containing streptococci and yet slight local disturbance result. On the other hand, during an operation on a patient with puerperal septic infection a small puncture of the epidermis may result in grave local and constitutional symptoms. When septicemia originates from infected thrombi, the infection elements, in the writer's opinion, are diffused to a great extent through the lymph channels. In acute bacteremia, there is usually but one chill or in some instances there is none. The infection is intense and occurs suddenly. There is usually no repetition of the chill because the rapidly multiplying organisms are already in large quantities in the circulation.

In chronic bacteremia, on the other hand, there are repeated chills, due to fresh additions of septic organisms into the system. The pathological differences found on autopsy are well known, and harmonize with the manner in which the pathological germs are introduced into the system. It is impossible to distinguish septicemia from pyemia by a bacteriological examination of the blood or tissues. The author proposes for simplicity to limit the term "septic infection" to "local sepsis," reserving the term "acute bacteremia" for what is ordinarily called septicemia, and the term "chronic bacteremia" for "pyemia," so called.

Both acute and chronic bacteremia are caused by microscopic organisms, but one is of short duration, the other long. So much then for the definitions of the terms to be used in the second part of the paper.

If the definitions and the pathological changes of acute bacteremia are kept in mind, it should be evident that surgical intervention, like extirpation of the uterus, whether performed by abdominal or vaginal route or an abdominal section with drainage, must be futile. The author believes that it is a common error to report cases of local sepsis with severe constitutional symptoms as cases of acute bacteremia, and thus

much confusion is caused. In this way it has been claimed that hysterectomy for acute bacteremia has been followed by recovery. In the opinion of the writer no such result ever has been or ever will be achieved by the surgical intervention alluded to for the cure of acute bacteremia. If ever we should be fortunate enough to find a remedy for acute bacteremia it will be found in the realm of serumtherapy. The writer then said that this decisive assertion had been verified by clinical experience extending over the past 18 years. During this time he had performed all of the major operations on a large number of patients, yet he had not seen a single instance of recovery from acute puerperal bacteremia (general puerperal sepsis), even if operations had been performed. In his opinion the only effect from the operations on such patients was to hasten death. Dr. Boldt continued to perform the various operations for acute bacteremia, thinking that it might be possible to save life, because others had maintained that they had been successful; but it is evident to him that those who made those assertions were mistaken in the view as to what bacteremia (septicemia) is. There is no doubt, however, that the operations alluded to in the title of the paper are indicated in some patients ill with septic infection.

It is then of the greatest importance to know when to operate, and for what conditions. It is not easy to make exact diagnosis, but, as a rule, we can come to a correct conclusion after observing the course of symptoms for several days. Some patients ill with sapremia will show such severe symptoms that they simulate acute bacteremia, but a short observation will usually decide the question. Occasionally patients who suffer from toxemia (sapremia) may present positive indications for the removal of the organ giving rise to the infection. To illustrate, B. S. Schultze, in the *Deutsche medizinische Wochenschrift*, 1886, No. 44, mentions the following case: The patient was delivered of a dead child on September 7, the placenta did not follow, and upon traction the cord tore off. The physician could not reach the placenta to remove it. In the hospital it was found impossible to remove it, even under full anesthetics. She began to show symptoms of infection two days after delivery, and her condition became much worse. She had frequent chills and high temperature, so that it was evident that she would die if the cause of the infection could not be removed, especially as peritoneal irritation had begun. On September 13 a supravaginal amputation was made. The uterine bicornis was gangrenous nearly to the peritoneal cavity. The patient recovered. Another case was reported by Sippel (*Centralbl. f. Gynäk.*, vol. 18, p. 667) in which the placenta was removed by manual extraction, but some placental fragments remained which Sippel could not remove, because of the softened condition of the uterus. The patient was extremely anemic from blood-loss which was large. Septic endometritis resulted, and 13 days subsequent to delivery supravaginal amputation was performed, recovery resulting. An infection by microscopic organisms had been added to the toxic infection by saprophytes, an occurrence not uncommon in sapremia. In such cases the reader favors total extirpation to supravaginal amputation, for the reason that the peritoneum can be protected from infection by approximate safeguards.

In cases of septic infection the author has based his blood investigations entirely upon smear preparations, obtained from a finger, and these were unsatisfactory. In two instances when streptococci were finally found, previous examination having proved negative, the patient succumbed. In 3 successful instances in which indication for operation was based on clinical conditions, the blood examinations were negative, the second alone showing streptococci. It would not in his opinion be just to the patient to wait always for operation until positive evidence was found in the blood. The writer then mentioned a case which had occurred in his consultation practice in 1893. He had seen a patient 3 weeks after delivery who had shown all the symptoms of acute septicemia. The physician had not curetted, but relied solely on vaginal douches, stimulants and quinin. When seen by Dr. Boldt, the patient was greatly emaciated, temperature 103, pulse 124 and feeble. There was no exudate in the pelvis, but the uterus was large, boggy and sensitive to touch. Examination of the interior of the uterus did not reveal the presence of placental tissue. After the examination the patient had a severe chill, temperature rose to 105.8° pulse to 156. In view of the gradual sinking of the patient, the irregular chills, fever, the size and consistency of the

uterus, the condition was diagnosed as septic metritis, and hysterectomy performed the following morning.

The diagnosis proved correct, the tissues of the uterus tearing as if decomposed. The patient had no more chills, the highest temperature after the operation was 101, and recovery was uninterrupted. Under similar conditions even with a negative result of blood examination, the writer would adopt the same course today. It is impossible with our present knowledge to lay down absolute rules for the performance or omission of the operation of hysterectomy, but for general guidance I would advise the following indications for hysterectomy, if it is evident that less heroic treatment is useless:

I. If after a full term delivery, or an abortion, there are no conception products in the uterus and the patient has fever with exacerbations, chills, a small and frequent pulse (120 to 140 or more), if careful observation should show that the infection comes from the uterus alone, that organ being enlarged, and relaxed in its consistency, if there is no evidence of peritonitis, the parametria free, if streptococci are found in the uterus, and, especially, if the blood shows the presence of pathogenic germs.

II. If there are decomposition products in the uterus, as in the instances reported by Schultze, Prochownik, Stahl and others, which cannot be removed satisfactorily per vaginam; if on doing a cesarean section the uterus is found septic, then an abdominal hysterectomy is indicated. Abdominal section with drainage is indicated in diffuse septic peritonitis, when there is no evidence of an exudate in the pelvis. The adnexa are to be left undisturbed unless there is a positive indication to do otherwise.

In the discussion Dr. VINEBERG said that he agreed with Dr. Boldt in his indications for hysterectomy, but that he personally preferred the abdominal route to the vaginal. He could not agree with the reader of the paper with regard to the definitions of sepsis. He thought there were no grounds for the introduction of the term bacteremia. To his mind there was but one kind of infection. Many times, from neglect, putrid intoxication runs into acute septicemia, and the profession should be taught that each case of sapremia is one of septic infection from the onset, and that it may pass into acute septicemia. Infection with other bacteria, such as the *Bacillus coli communis*, the staphylococci, and the *Bacillus aerogenes capsulatus*, have also been attended with fatal results. Dr. STONE congratulated the reader of the paper, on his successful effort to pick out and define the different varieties of puerperal infection. To his mind the profession was too apt to think that there was only one form of sepsis, and that the correct thing to do in each case was to curet. This he thought a great mistake, as many cases get well without curettage. Dr. ABRAM BROTHERS thought that the question of treatment depended upon the recognition of the presence or absence of local infection. This infection may be due not only to placental debris after delivery, but to some condition of local infection occurring previous to delivery. He agreed with Dr. Boldt that if the diagnosis of acute bacteremia can be made, hysterectomy or any other form of local treatment is contraindicated. In his opinion the terms "local sepsis," "acute bacteremia," and "chronic bacteremia" were well chosen. Dr. W. E. PORTER said he believed that many cases would not come to hysterectomy if persistent intrauterine irrigations were properly carried out. In his experience the placental forceps were better than the curet for the removal of retained secundia. Dr. MALCOM McLEAN had seen several cases in which lactation had given symptoms severe enough to make one strongly suspect septic infection, and he advises the greatest caution in making the diagnosis which would result in the performance of hysterectomy. Dr. G. L. BRODHEAD referred to the cases of hysterectomy for retained placenta, which Dr. Boldt had reported, and said that in his opinion if retained placenta could not be reached by the usual methods, it would be better to incise the cervix in order to get more space in which to operate. Certainly the greater part of retained placenta could be removed in this way and therefore hysterectomy would never be indicated. Dr. JANVIN said he had never removed a uterus for acute septicemia, but that he should like to ask Dr. Boldt to tell how one should know whether to perform abdominal or vaginal hysterectomy. Dr. BOLDT in closing said that he would again refer to the excellent definition given by Coplin

under the term "mycosis of the blood." We must recognize the fact that puerperal fever is always in a degree a septic infection. If fetid discharges come from the vagina, it does not necessarily mean that the case is a serious one. Patients with acute bacteremia may have no fetid discharge, and yet there may be an intense septic endometritis. We must watch our cases for a number of days or several weeks, and if we find that all treatment has failed, the patient is steadily getting worse, no other cause for the chills, etc., can be found, where the parametria are free, and there is no peritonitis, where perhaps streptococci are found in the uterine secretions, then, under these conditions, we are justified in considering vaginal hysterectomy. Abdominal hysterectomy should be considered only in cases where we are called upon to perform a cesarean section on a septic uterus, or where there is an intense septic intoxication associated with a septic endometritis, the patient's condition not improving under other treatment. The reason why the placenta could not be removed in the case reported by Schultze was on account of there being a uterus bicornis. In the other case, quoted from Sippel, the general condition of the patient was such that it was not advisable to carry on intrauterine manipulation further, so great was the danger of perforation. In conclusion, Dr. Boldt said that it required great judgment to decide in these cases what was correct to do, but that each must judge from his own experience with the aid of all the symptoms present. We should all endeavor to make definite definitions of the diseases that we are dealing with.

NEW ENGLAND.

Diphtheria at the Navy Yard.—The receiving ship *Wabash*, the marine barracks and the naval prison at the Charleston Navy Yard have been quarantined by order of Admiral Sampson. The quarantine has been established to prevent the spread of diphtheria.

WESTERN STATES.

Wesley Hospital.—Dr. R. D. Sheppard, of Northwestern University, received two donations to Wesley Hospital on February 8, 1901, one of \$5,000 and one of \$1,000.

College is Quarantined.—Ellsworth College, of Iowa Falls, was placed in quarantine on account of smallpox. Over 100 students and professors are restrained.

University Closed on Account of Scarlet Fever.—The faculty of the University of Wooster, Mo., dismissed all the students for two weeks on account of one young woman who had contracted scarlet fever.

New Hospital.—A new hospital, to cost \$125,000, and which in convenience of appointments and completeness is expected to have no superior in the Northwest, is about to be erected in Baker City, Oregon. It will be under the direction of the Sisters of St. Francis.

Prize Essay on the Dangers from Quackery.—The Colorado State Medical Society offers a prize of \$25 for the best essay, if deemed worthy of the prize, pointing out the dangers to public health and morals, especially to young persons, from quackery as promulgated by public advertisements. The competition is open to all. Essays must be type-written in the English language, and submitted before May 15, 1901. Each essay must be designated by a motto, and accompanied by a sealed envelope, bearing the same motto, and enclosing the name and address of the author. The essay receiving the prize will become the property of the Society for publication. Others will be returned on application. Essays should be sent to the Literature Committee, Room 315, McPhee Building, Denver, Colorado.

SOUTHERN STATES.

Dr. E. G. Hill has been elected secretary of the Manchester, Va., Board of Health.

Richmond (Va.) News.—The Hunter McGuire Memorial Association has raised about \$400. When the amount has been somewhat increased, it is proposed to erect a monument to this distinguished surgeon in one of the public parks.

Appointment.—Dr. W. D. Bacon has been appointed resident physician of the Baltimore University Hospital in place of Dr. W. R. Stover, who recently resigned. Dr. Edwin Moriarty has been appointed assistant resident physician to succeed Dr. Bacon.

Vaccination of School Children.—The Louisiana State Board of Health has addressed a circular letter to all superintendents of parish public schools, all presidents of parish boards of public education, all principals of parish public schools, presidents of State educational establishments, and to the press of the State, calling attention to the following resolution adopted by the board:

Be it Resolved, That copies of the law be printed requiring the vaccination of public school children, and sent to each superintendent of public schools, as well as the presidents of all educational institutions receiving public moneys.

This circular is intended to meet the danger resulting from the prevalence of smallpox in certain sections of this and adjoining States.

In Memory of Dr. Rohe.—A memorial meeting to the late Dr. George H. Rohe, who died two years ago, was held February 6 by the Medical Society of the College of Physicians and Surgeons of Baltimore in the college amphitheater. The president, Mr. J. M. Barry, of the graduating class, presided. Addresses concerning the life and work of Dr. Rohe were made by Professors William Simon, Aaron Friedenwald and J. W. Chambers. Short tributes were paid to the memory of Dr. Rohe by Drs. Henry M. Hurd, Wilmer Brinton, William R. Stokes, Thomas A. Ashby, H. H. Biedler, and John F. Crouch.

MISCELLANY.

Holding Consumption in Check.—Deaths from consumption in Philadelphia are estimated to be one-third less than they were 15 years ago. The health authorities say the improvement is due to their continuous battle against the disease.

Medical Certificates for Immigrants.—The bill amending the immigration laws so as to exclude persons affected with insanity, idiocy, or epilepsy was favorably reported February 5, from the House committee on immigration and naturalization. The bill requires a medical certificate from immigrants showing freedom from these ailments and requires steamship companies to deport immigrants found to be incapacitated in this respect.

Scarcity of Naval Surgeons.—There appears to be a prevailing embarrassment in the navy because of the inability of the medical corps to secure competent young physicians as assistant-surgeons. The army seems to be preferred on account of the higher rank which it offers and the better prospects for the future.

Obituary.—DR. J. C. CARPENTER, of Sherman, Tex., on February 3, 1901, aged 85 years.—DR. JOHN HUNDLEY, at Montague, Md., on January 30, 1901, aged 75 years.—DR. CLAYTON A. COWGILL, at Philadelphia, Pa., on February 5, 1901, aged 75 years.—DR. JAMES A. SHUTTLEWORTH, at Pleasant Hill, Mo., on February 2, 1901, aged 88 years.—DR. HENRY C. HILL, Assistant Surgeon of the 128th New York Volunteers, at Lockport, on February 8, 1901, aged 69 years.—DR. JAMES T. PERKINS, of Springfield, Md., on January 30, 1901, aged 47 years.—DR. S. H. CADE, of Negreet, La., on February 7, 1901.—DR. WILLIAM P. MANNING, of Washington, D. C., on February 9, 1901, aged 56 years.—DR. M. G. CUNNINGHAM, at Binghamton, N. Y., on February 11, aged 48 years.—DR. FRANK BOND, at Brooklyn, N. Y., on February 10, aged 74 years.—DR. LEVI ROYER, at New Windsor, Md., on February 10, aged 62 years.—DR. PETER MOIR BARCLAY, at Newburg, N. Y., on February 11, aged 67 years.—DR. SAMUEL C. BUSEY, of Washington, D. C., on February 12, aged 72 years.—DR. WISE, at San Francisco, Cal., on February 3, 1901.—DR. JOHN STUART WOODSIDE, at Chester, Ill., on February 11, 1901.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended February 9, 1901:

Changes in the Medical Corps of the U. S. Army, for the week ended February 9, 1901:

MACDONALD, CHARLES E., acting assistant surgeon, is assigned to temporary duty on the transport "Oopack" during the voyage to the Philippines. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

BAILEY, GUY G., acting assistant surgeon, leave of absence granted January 9 is extended 14 days.

BELT, HARRY D., acting assistant surgeon, having relinquished the unexpired portion of the leave of absence granted him January 18, will proceed from New York City to Fort Trumbull, and report for temporary duty.

The following named acting assistant surgeons will proceed from the places hereinafter designated to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where upon arrival they will report to the commanding general, division of the Philippines, for assignment to duty: POLK D. BROWN, Hartsville, Tenn.; HENRY M. HALL, Cedar-town, Ga.; MELVILLE A. HUGHES, Washington, D. C.; EDGAR W.

MILLER, Chicago, Ill.; FRANK W. PEASE, Wahpeton, N. D.; JULIUS M. PURNELL, Paris, Ky.; ANTON R. SCHIER, Oconomowoc, Wis.

DEVEREUX, J. RYAN, acting assistant surgeon, is detailed as a member of the board of officers at Washington Barracks for the examination of officers for promotion, vice Captain Edward L. Munson, assistant surgeon, relieved.

CLOSSMAN, AUGUST VON, acting assistant surgeon, now at St. Louis, Mo., will report in that city to Major Thomas F. Davis, Twelfth Infantry, recruiting officer, for duty as examiner of recruits.

HORNE, WILLIS S., acting assistant surgeon, will proceed from Marlin, Tex., to San Antonio, Tex., and report to the commanding officer, department of Texas, for assignment to duty.

KEAN, Major JEFFERSON R., surgeon, will proceed to Washington, D. C., and report on February 4 to the president of the board of officers convened in that city for examination as to his fitness for promotion.

A board of medical officers to consist of Colonel ALFRED A. WOODHULL, assistant surgeon-general; Major LOUIS A. LE GARDE, surgeon; Captain WILLIAM C. BORDEN, assistant surgeon; Captain FRANK R. KEEFER, assistant surgeon, is appointed to meet at the Army Medical Museum building, Washington D. C., February 11, for the examination of candidates for admission to the medical corps of the Army.

A board of medical officers, to consist of Lieutenant-Colonel BENJAMIN F. POPE, deputy surgeon-general; Lieutenant-Colonel ALFRED C. GIRAUD, deputy surgeon-general; Major ROBERT J. GIBSON, surgeon; Captain WILLIAM H. WILSON, assistant surgeon, is appointed to meet at the U. S. General Hospital, Presidio, Monday, February 11, for the examination of candidates for admission to the medical corps of the Army.

GIRAUD, Major JOSEPH B., surgeon, is granted leave of absence for 1 month, on account of sickness.

HARTSUFF, Colonel ALBERT, assistant surgeon-general, retirement from active service, February 4, 1901, under provisions of act of Congress, approved June 30, 1882, is announced.

WOOD, Major MARSHALL W., surgeon, will proceed to St. Louis, Mo., and take temporary charge of the medical supply depot at that place during the absence of Major Joseph B. Girard, surgeon, and upon the return of the latter officer will rejoin his proper station.

WALSH, JOSEPH W., acting assistant surgeon, will proceed from Brooklyn, N. Y., to Washington Barracks and report at the U. S. General Hospital at that post for duty.

BANTA, WILLIAM P., acting assistant surgeon, now on temporary duty at the U. S. General Hospital, Presidio, is relieved from further duty in the division of the Philippines and will report to the commanding general, department of California, for assignment to duty at that hospital.

The following-named acting assistant surgeons are relieved from duty at the U. S. General Hospital, Presidio, and will report to the commanding general, department of California, for assignment to duty with troops en route to the Philippine Islands, where they will report to the commanding general, division of the Philippines, for assignment to duty: WILLIAM ALDEN, EDWARD A. SOUTHALL.

SCHUMACHER, FREDERICK, hospital steward, is assigned to temporary duty with troops on the Army transport "Lawton." Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

PEDLAR, A. J., acting assistant surgeon, is granted leave of absence for 1 month.

CUTTER, J. B., acting assistant surgeon, is granted leave of absence for 1 month.

CARROLL, JAMES, acting assistant surgeon, will proceed from Columbia Barracks, Cuba, to Washington, D. C., and report to the Surgeon-General of the Army for duty in the pathological laboratory of the Army Medical Museum at the latter place.

DELANEY, MATTHEW A., acting assistant surgeon, will proceed from the National Soldiers' Home, Va., to Fort Monroe for temporary duty.

EDIE, GUY L., surgeon, now in San Francisco, Cal., is relieved from further duty in the division of the Philippines, and will report to the commanding general, department of California, for assignment to temporary duty in that department.

Changes in the Medical Corps of the U. S. Navy, for the week ended February 9, 1901:

GUTHRIE, J. A., passed assistant surgeon, detached from the "Franklin," and ordered to the "New York," February 18.

McCORMICK, A. M. D., surgeon, detached from the Naval Hospital, Norfolk, Va., and ordered to the Naval Academy.

SPEAR, R., passed assistant surgeon, detached from the "Buffalo," on arrival at Cavite, and ordered to the "Isla de Luzon."

GROVE, W. B., assistant surgeon, detached from the "Vermont" and ordered to the Naval Hospital, New York.

BUCHER, W. H., assistant surgeon, detached from the Naval Hospital, New York, and ordered to Naval Hospital, Norfolk, Va.

STONE, M. V., assistant surgeon, detached from the "Isla de Luzon," and ordered to the "Buffalo."

DEBB, E. Z., medical inspector, ordered from the Naval Academy, February 14.

DuBOSE, W. R., surgeon, detached from the Naval Academy, February 13, and ordered to the "Wisconsin."

BERTOLETTE, D. N., medical inspector, ordered to the "New York," February 16.

Changes in the U. S. Marine-Hospital Service, for the week ended February 7, 1901:

BAILHACHE, PRESTON H., surgeon, relieved from duty as chairman of the board for the physical examination of Second Assistant Engineer R. F. HALPIN, R. C. S. February 4.

VAUGHAN, G. T., surgeon, detailed as chairman of the board for the physical examination of Second Assistant Engineer R. F. HALPIN, R. C. S. February 4.

CORPUS, G. M., assistant surgeon, Bureau order of January 26, directing Assistant Surgeon Corput to proceed to Cleveland, Ohio, for temporary duty, revoked. February 2.

FRANCIS, EDWARD, assistant surgeon, to proceed to Cleveland, Ohio, and assume temporary command of the service during the absence on leave of Surgeon Pettus. February 2.

CALLAID, J. C., acting assistant surgeon, granted leave of absence for 5 days from February 7. February 4.

Foreign News and Notes.

GREAT BRITAIN.

Dr. W. H. Willcox, has been appointed lecturer on chemistry and physics at St. Mary's Hospital Medical School.

Dr. Walter Myers, of the Liverpool School of Tropical Medicine, who has been carrying out investigations of yellow fever, has fallen a victim to his scientific devotion.

The death of Mr. Bowater John Vernon, F.R.C.S. Eng., the senior ophthalmic surgeon to St. Bartholomew's Hospital, is announced. He was also ophthalmic surgeon to the West London Hospital.

Royal College of Surgeons.—The following candidates passed the final examination for the Fellowship at the last half-yearly meeting of the examiners, and have been admitted Fellows of the College in the order of their seniority as members, viz.: Messrs. Frederic Pinsent Maynard (Major I.M.S.), M.B.Durh., L.R.C.P.Lond., D.P.H.Camb., St. Bartholomew's Hospital, member April 28, 1885; Edgar Godfrey Carpenter, L.R.C.P.Lond., D.P.H.Camb., St. Bartholomew's Hospital, member August 1, 1889; John Herbert Parsons, M.B., B.Sc.Lond., L.R.C.P.Lond., University College, Bristol and London and St. Bartholomew's Hospital, member, November 12, 1891; Elmore Wright Brewerton, L.R.C.P.Lond., St. Bartholomew's Hospital, member February 7, 1895; Alexander Gordon Wilson, M.B.Lond., L.R.C.P.Lond., London Hospital, member May 13, 1897; Edward Septimus Earnshaw Hewer, L.R.C.P.Lond., St. Bartholomew's Hospital, member February 10, 1898; Irwin Walter William Hunter, M.A., B.Sc.Otago, L.R.C.P.Lond., Otago University, New Zealand, and London Hospital, member May 4, 1898; Percy William George Sargent, M.A., M.B., B.C.Camb., L.R.C.P.Lond., Cambridge University and St. Thomas' Hospital, member May 4, 1898; Thomas Alfred Mayo, M.B.Camb., L.R.C.P.Lond., Cambridge University and St. Bartholomew's Hospital, member November 10, 1898; William Archibald Logan, M.B., Ch.B.Dunedin, L.R.C.P.Lond., Dunedin University, New Zealand, and King's College, London, member July 27, 1899; James Sherren, L.R.C.P.Lond., London Hospital, member July 27, 1899; Robert James Johnston, B.A., M.B., B.Ch., R.U.I., Queen's College, Belfast, and Royal University of Ireland, not previously a member.

CONTINENTAL EUROPE.

The Nineteenth Congress for Internal Medicine will be held in Berlin April 16-19, 1901.

Dr. Karl Haegler and **Dr. Friedrich Egger** have been appointed extraordinary professors of medicine in the University of Basel.

Dr. Martin Hahn has been commissioned by the Bavarian Government to proceed to Egypt and India for the purpose of studying the plague.

Society Report.

THIRD PAN-AMERICAN MEDICAL CONGRESS.

Held at Havana, Cuba, February 4, 5, 6 and 7.

[From our Special Correspondent.]

THE formal opening general session was held at 8.30 o'clock this evening at the "Gran Teatro de Tacon" and was presided over by Military Governor General Leonard Wood, who, in a few well-chosen words, welcomed the delegates to the City of Havana and to the Island of Cuba. The Tacon Theater bears the name of a celebrated captain-general of the island. It is on the west side of the Prado and fronts on Central Park. It was built by Senor Francisco Morti in 1837 at a cost of 500,000 centenes in gold coin, or about \$2,000,000, was named after General Tacon, and is now owned by an American syndicate. Its auditorium is in the shape of a horseshoe and was handsomely decorated. The 70 boxes and six balconies contained hundreds of beautifully attired ladies, while the magnificent chandelier dependent from the ceiling in front of the stage with its 1034 gas jets brilliantly illuminated a most imposing spectacle. The entire total capacity of the theater is about 4000. Many delegates occupied seats upon the platform. Among those from the United States were noticed: Drs. A. M. Phelps, L. A. Pilcher, and B. T. Whitmore, of New York; Liston H. Montgomery, Chicago; Joseph Mullen, Houston, Tex.; J. W. Holliday, Burlington, Ia.; Roland G. Curtin, Philadelphia; Enoch Hollingshead, Pemberton; and William J. Chandler, South Orange, N. J. Beside these were Dr. John Guitéras, Havana; Dr. John Santos Fernandez, President of the Congress; Dr. Thomas V. Coronado, Secretary-General; Dr. Eusebio Hernandez, and probably fifty others, including the Mayor, Hon. Alexander Rodriguez. Many pretty tropical plants surrounded the speaker's platform and embellished the stage, which presented a very pleasing appearance. The entire opera house was well nigh filled with the elite of Havana's 260,000 inhabitants, nearly all of whom were in evening dress. The history of the Congress was then read by Dr. Coronado.

He was succeeded by the president, who dwelt much upon the progress of medical science in Cuba.

Great regret was felt at the absence of Dr. C. A. L. Reed, secretary of the International Executive Committee, who was announced on the program for an address of a scientific nature. (Subject not announced.)

Dr. E. Hernandez, of Havana, then spoke extempore for 40 minutes. Among the numerous expressions he used was: That the general practising physician should be held in great respect by the community where he dwells for his watchfulness in public health matters.

Everything was said and done according to the latest approved Spanish style. A good-sized orchestra interspersed superb music.

Section on General Medicine.

Dr. Carlos A. Finlay, Havana, presiding. The important paper in this section today was read by Major Walter Reed. For his investigations of the relation of the mosquito to yellow fever, see the Manual. Among other statements in his paper was the description of how Camp Lazear had been established at Quemados, which was strictly quarantined so that the experiments could be carried out successfully. Drs. Reed, James Carroll, and Agramonte of the board, at first confined their operations to themselves, and were so enthused with the success of their investigations that they carried out their work still farther by obtaining volunteers to submit to their experiments which showed that the fever was promulgated by the *Culex fasciatus* (genus *stegomyia*) which had been allowed to bite a yellow fever patient, and subsequently allowed to bite a nonimmune who had been carefully quarantined. Sixty-five per cent. of the experiments resulted in well-defined cases of fever (bitten by the female *culex*). To prove this theory, Dr. Reed showed that the *culex* was to be found in all countries where yellow fever existed, and that it was never found where yellow fever did not exist.

In these cases the mosquito did not inoculate the non-immune until between the twelfth and twentieth day after it had bitten the patient. Subcutaneous and intravenous injections of blood taken from a yellow fever patient would produce the disease in a nonimmune.

Said the speaker, the present quarantine laws against yellow fever were needless. We need not scrub with bichlorid solutions, nor disinfect, fumigate or freeze a cargo, merchandise, trunks, bedding, etc. To prove this, at Quemados, non-immunes were dressed in clothing taken from yellow fever patients, and had slept on bedding used by them, and that not one case had developed from this exposure. The detention system therefore was absurd and of no avail whatsoever.

The effective way, therefore, to prevent carrying of the fever was the destruction of the mosquitoes which might have reached a boat. The moral side of the question of subjecting human beings to experiments was dwelt upon, and in all cases that they had experimented upon,—twenty all together—in each instance the subject had explained to him the danger of the process, but in each case the full cooperation of the patient was secured. The paper elicited much discussion. Among those participating were Drs. Finlay, Agramonte, John Guitéras, L. H. Montgomery, of Chicago, H. B. Horlbeck of Charleston, S. C., and Ryder, of Havana.

Dr. Agramonte followed by reading his report, or rather the combined report—which was the same repeated. Both he and Dr. Carroll deserve an equal amount of credit for these investigations and experiments.

INTERMEDIATE SESSION.

The second intermediate or general session of the Congress was held at 8.30 o'clock this evening at the Marti Theater, with the president, Dr. Fernandez, in the chair.

This is a handsome summer garden and theater in the block south of the Pasaje hotel and opposite Parque de Isabel La Catolica. It is commodious and well ventilated. It seats about 1,200 persons.

The business of this second general session, while of a semi-formal nature, was transacted entirely in Spanish. All the speakers read from manuscript. Many ladies occupied the tier of boxes throughout.

The first address of the evening, scientific in character, was delivered by Dr. Gustavo Lopez, vice-president of the Congress, and secretary of the Academy of Medical Sciences. He stood upon a mounted stand erected for the purpose embellished with Cuban colors. His voice was faint, audible only to those nearest to him. Nowhere throughout the theater was there evidence of the Stars and Stripes, and not a flower adorned the platform.

During the interval before the next speaker a lively musical selection was rendered by the orchestra.

Dr. Eduardo Wilde, minister plenipotentiary of the Argentine Republic at Washington and City of Mexico, delivered the next address from manuscript. He closed amidst plaudits followed by orchestral music.

The last address of the evening was of a scientific character, by Dr. Louis H. Debayle, official delegate of the Republics of Nicaragua and Honduras, after which the audience adjourned.

General Session.

Dr. J. S. Fernandez presided. He said Congress desires countries to unite in stamping out yellow fever.

As a result of the remarks in the address delivered on Tuesday evening at the General (intermediate) Session by Dr. Wilde, the Argentine Minister to Washington and the representative of his government at the Congress, treating upon maritime hygiene, a general meeting was held this forenoon of all the Sections in the great hall of the University building. It was a largely attended meeting, and it was unanimously resolved to accept the motion proposed by Dr. Wilde in his address with slight modifications, as the Executive Committee might consider advisable, namely: To convene an International Health Congress which shall be composed of delegates representing the various governments of America which may recognize the call. The mission of the Congress will be to propose a plan for a treaty in which ways and means will be advanced for the suppression of yellow fever at the places of its origin, and in places where it exists.

Dr. Porter, of Key West, Fla., without having been ap-

prised of the scope of Dr. Wilde's paper, proposed a few hours later to Dr. Fernandez a series of resolutions having the same object in view.

After considerable discussion it was decided to incorporate Dr. Porter's resolutions with those of Minister Wilde.

This step was regarded as an important measure taken by the Congress, and was compared by many to the well-verified experiments of Drs. Reed, Carroll and Agramonte on the mosquito as a means of propagating *febrilla amarilla*.

If the theory is correct that mosquitoes are the prime cause of the disease, an international quarantine organization will undoubtedly eradicate this frequently fatal malady and give rise to a less restricted commerce and traffic, thus greatly facilitating trade between the United States and infected West Indian, Central, and South American ports.

This topic was discussed in detail by Secretary Tamayo, Drs. Horlbeck, Agramonte, Fernandez, Wilde, Bennett, Porter, DeBaile, Calmek, and others.

After some remarks endorsing Dr. Horlbeck's article, in which allusion was made to the pressing necessity for a continuous effort in bacteriological work in respect to the question of etiology and mode of transmission of yellow fever, Dr. Joseph N. Porter, State Health Officer of Florida, offered the following resolutions:

Resolved, That this section of Maritime Hygiene and Quarantine of the Pan-American Medical Congress, now being held in the city of Havana, recommends that an International Commission of Bacteriologists and quarantine officials of extended experience be created to study the etiology and manner of transmission of yellow fever, and that the countries most interested in this subject defray the equipment and maintenance of said commission.

Resolved, Also that the commission thus created shall report detailed results of its labors and investigations to the next meeting of the Pan-American Medical Congress.

Section on General Medicine.

Among the notable papers read at this forenoon's section was one by Dr. Liston H. Montgomery, of Chicago, entitled, "Need of a Department of Health as a separate branch of the Federal Government with a physician at its head as secretary, to rank with parity and equal dignity as the other members of the President's Cabinet."

GENERAL OR INTERMEDIATE SESSION.

This was the closing general session held at the Marti Theatre. Among other business transacted was the resolution submitted by Drs. Roland G. Curtin and G. Hudson Makuen, of Philadelphia, upon the death of Dr. William Pepper, they having been appointed by a meeting of representative physicians from the United States at a called meeting held on Wednesday morning at the University, as their expression of sorrow. The resolution follows:

"It is with unfeigned sorrow that we mourn the untimely death of our honored president, Dr. William Pepper, who organized the Pan-American Medical Congress, and so ably and successfully presided over the first two meetings. To his wise supervision is due much of the success of the Congress since its inception. At this time we especially feel the loss of his guiding hand and executive ability to help us in achieving still greater success. In our grief we are not alone, for many and varied enterprises are hampered by the absence of his painstaking care. Among the more prominent may be mentioned the Congress of American Physicians and Surgeons, the University of Pennsylvania, the Commercial Museum (a great and original conception of his own), and the Archeological Museum of Philadelphia. Let his example of untiring industry and the memory of his useful life spur us on to carry out the important work planned by our beloved president, Dr. William Pepper. May the crown of glory, which he richly deserves, be his is the prayer of his associates of the Pan-American Medical Congress."

The resolution was adopted by a rising vote.

Dr. Walter C. Wyman read an elaborate address—"Municipal Sanitation and Cleanliness"—which dwelt largely upon infection, contagious and loathsome diseases, and how best to eliminate this class of maladies. He deprecated the present method of maritime quarantine in the detention of ships containing valuable cargoes, etc. Fresh air and sunshine, good food and cleanliness, are among the best remedies

to ward off infection. Sanitary improvements should be backed up by capital, the same as public libraries and charitable institutions—perhaps on the endowment plan—or capital thus employed should be devoted to building better homes for the poor. Philanthropists should do this. He hoped much would be done in this direction during the twentieth century.

Dr. A. Vandever, of Albany, N. Y., responded in behalf of the registered members of the Executive Committee of the United States in the absence of Dr. C. A. L. Reed, who was detained by serious illness in his family from being present. He thanked the committee and profession of Havana for the excellent arrangements. The committee desired to express its approbation to the ladies' committee for the kindly care they had manifested in looking after visiting ladies.

It was his good fortune to attend the congress held at Washington and in Mexico, but for real scientific work neither of those compared with this meeting. And during this twentieth century a great work will be going on in the investigation of the etiology of yellow fever right here in Havana. This congress was organized for the specific purpose of studying contagious diseases. None of the Republics except Mexico had contributed anything towards studying *flora*, and she had appropriated \$500 for this purpose.

Again he renewed and voiced the committee's expression for the excellent receptions and hospitality which had been extended to us, and for the truly scientific work which had been done by the congress.

NOTES ON THE CONGRESS.

About 75 were present from the United States and about 325 from Cuba, Mexico, Honduras, Costa Rica, and other Central and South American countries. Among those present from the United States were: G. Hudson Makuen, Roland G. Curtin, Philadelphia; A. M. Phelps, Ramon Guitéras, Reginald G. Sayre, F. C. Valentine, Charles Roberts, Thomas E. Ranford, H. A. Komeman, Charles E. Bruce, B. T. Whitmore, New York; H. L. E. Johnson, Walter Wyman, Washington; George H. Simmons, Liston H. Montgomery, E. Wyllis Andrews, Henry T. Byford, Henry P. Newman, Frank C. Greene, Chicago; George N. Kreider, Levi S. Pilcher, Springfield, Ill.; Thomas L. Stedman, J. L. Medina, New York; Joseph Y. Porter, Key West, Fla.; E. Vanhook, J. F. Gillet, Okala, Fla.; T. A. Stoddard, Puebla, Col.; William Perrin Nicholson, George H. Noble, Atlanta, Ga.; S. C. Carson, Greensboro, Ala.; William H. Earles, Louis F. Frank, Milwaukee, Wis.; Joseph Mullen, Houston, Tex.; J. Bennett, Austin, Tex.; J. T. B. Berry, Brandon, Miss.; J. S. Foote, Omaha, Neb.; W. Stuart Carnes, Canton, O.; W. J. Gillette, Toledo, O.; W. E. B. Davie, Birmingham, Ala.; William M. Findley, Altoona, Pa.; E. Hollingshead, W. C. Parry, Pemberton, N. J.; Henry Mitchell, Newark, N. J.; A. Vandever, Albany, N. Y.; A. H. Nichols, Boston, Mass.; J. D. Griffith, Kansas City, Mo.; H. B. Horlbeck, Charleston, S. C.; H. T. Young, J. W. Holiday, Burlington, Ia.; N. C. Morse, Eldora, Ia.; Wm. Jepson, Sioux City, Ia.; D. S. Fairchild, Clinton, Ia.; Thomas McDavitt, St. Paul, Minn.; J. B. M. Gaughey, Winona, Minn.; T. D. Crothers, Henry Hammond, Hartford, Conn. Among others more notable were Eduardo Wilde, Washington, D. C., Rep. Argentine Republic; Thomas N. Calnek, San Jose, Costa Rica; Walter Reed, Carlos A. Finlay, James Carroll, Aristides Agramonte, John Guitéras, Alfonso Betancourt, Erastus Wilson, R. O. Mancour, Havana.

It was noted that no delegates were present from Canada, Maine, New Hampshire, Vermont, Washington, Oregon, New Mexico, Nevada, Montana, North or South Dakota, Kentucky, Tennessee, California, Kansas, Utah, Oklahoma, Arizona, Louisiana, Indiana, Arkansas, Maryland, Virginia, and West Virginia.

Of course the mosquito theory absorbed the greater portion of the discussion. The social functions were as elaborate as could possibly have been anticipated.

Among those specially worthy of mention was the reception by the military governor (Wood) of the island at the governmental palace on Monday, February 4, from 1 to 4 P.M.

A visit to the cigar and cigarette factories of Henry Clay and Bock Co., where 700 male and 500 female employees are engaged, was made on Tuesday, February 5, from 12 to 2 P.M.

A visit to Fort Cabana and Morro Castle, opposite the city, on Thursday, the 7th, at 3 o'clock P.M.

The grand ball at the Tacon Theater was given by the city government of Havana in honor of the foreign guests, members of the congress, on Friday evening, the 8th; 8,000 people were present of the elite of Havana. The refreshments served on this occasion were elaborate.

On Friday morning, the 8th, about 350 ladies and gentlemen visited Rosario, about 40 miles from Havana, where Mr. Ramon Pelyo gave the physicians a complimentary breakfast at one of the greatest sugar plantations in Cuba. The excursion was an exceedingly enjoyable one. His estate is a most magnificent one, and upon the arrival of the train of seven coaches at Aguacate Station we were welcomed by the school children, who, with flags and banners flying, waved their beckoning huzzas to the excursionists. The sight in some respects was pathetic. These children were of all colors, ages, sizes, etc., and were all neatly attired.

The grounds at this estate abound in flowers, plants, and many varieties of tropical fruit trees, like a veritable garden of Eden. Royal palms soared high. The coffee bush was covered with fragrant, white blossoms. The banana, orange, and coconut trees were all heavily loaded with fruit. A gigantic table in the form of a horseshoe was prepared, covered with snowy linen. A feature of the breakfast was the classical Spanish dish, rice and chicken. When the feast was over, toasts and vote of thanks, eloquent and profuse, were offered by the gentlemen from various countries. Dr. Ramon Guit  ras responded in behalf of the United States.

The authors of several papers, which were announced to be read by physicians from the United States, being absent, their papers will in due course appear in the published volume of proceedings, which is promised in about 6 months.

Dr. R. O. MARCOUR, assistant surgeon U. S. Navy, official delegate from the Navy Department, Havana, secretary Section on Marine Hygiene and Quarantine, read the first paper in this section on Monday, February 4, entitled, **Yellow fever and Sanarelli Serum** (see page 87 of the Manual). His was an exhaustive and interesting report of a grave case of yellow fever which he treated with Sanarelli serum. The case was a noteworthy one in so far as it was the first authentic case on record of a grave type of typhoid icterus where a patient had black vomit, and recovered under this method of treatment. The conclusion reached was that this patient would not have recovered had any other method been pursued. Several physicians on duty in Havana at the time saw the case in consultation with Dr. Marcour. The first organ which responded to the serum was the kidneys, second, the nervous system. The irritability of the stomach was quieted considerably. Toward the beginning of convalescence an erythematous eruption appeared first at the points where the serum was first injected, secondly, where the skin is thinnest, and later all over the body. This characteristic eruption was also observed in 2 other cases of yellow fever treated with the same serum by Dr. Marcour, but owing to the mild type of his other 2 cases he did not think them of sufficient importance to the medical profession to be noted and report same in detail. He referred to them several times while reading his paper. After the reading of his paper the President of the Section translated it into Spanish to the Cuban, Mexican, and South American physicians present. The paper elicited much discussion on the part of the foreign members. Dr. Marcour concluded by stating that we need to try the serum only in grave cases, since mild cases recover with simpler methods and good, careful nursing. The writer added that he is now convinced that the *Culex fasciatus* is the only agent capable of conveying yellow fever. The paper consisted of 38 pages of manuscript, and it is difficult therefore to abstract it and do the author justice, owing to the large amount of clinical data furnished therein.

A paper entitled **The operative treatment of prolapse and procidentia of the uterus** was read by Dr. HENRY T. BYFORD, of Chicago, Ill. (See page 75 of Manual for abstract.) He read his paper on February 4, before the Section on Gynecology and Abdominal Surgery.

The Angiotribe.—Dr. HENRY P. NEWMAN, of Chicago, Ill., described the use of his instrument on Thursday morning, February 7. (See page 72 of the Manual for abstract.)

A paper, **New operation for the radical cure of hernia**, was read by Dr. E. WYLLIS ANDREWS, of Chicago, Ill. (See Addenda of Manual.) The author read his paper on Thursday forenoon, February 7, before the Section of Gynecology and Abdominal Surgery as the Section on General Surgery had adjourned.

cology and Abdominal Surgery as the Section on General Surgery had adjourned.

A paper—**Summary of the progress made in the nineteenth century in the study of the propagation of yellow fever**—was read by Dr. CHARLES A. FINLAY, before the Section on General Medicine (president of the Section), on Tuesday forenoon, February 5 (see appendix of the Manual for abstract of his paper).

On Wednesday A.M., February 6, Dr. ERASTUS WILSON, Havana, Cuba, read **Municipal hygiene, or preventive medicine as required by the city of Havana** (see page 134 of the Manual for abstract), before the Section on General Hygiene and Demography.

On Monday forenoon, February 4, a paper—**Prevalence of glanders in Havana among the horses and people**—was read by Dr. HONORE E. LAINE, of Havana, Cuba, president of the Section on Veterinary Surgery. (See latter portion of Manual for Abstract.)

On Tuesday forenoon, February 5, Dr. JOSEPH MULLEN, Houston, Tex., read a report of a **Case of removal of the superior sympathetic cervical ganglion for non-inflammatory glaucoma** before the Section on Ophthalmology (see page 106 of the Manual for mention of title). This paper has been promised to the JOURNAL, hence will appear in its entirety in a subsequent issue.

On Wednesday forenoon, February 6, Dr. W. J. GILLETTE, of Toledo, Ohio, read a paper entitled **Present methods and tendencies in medical education in the United States** in the Section on Medical Pedagogy. (This paper is promised the JOURNAL, hence will be published in a subsequent issue.)

On Wednesday, A.M., February 7, Dr. T. D. CROTHERS, Hartford, Conn., read his paper on **Morphinism and crime**, in the Section on Diseases of the Mind and Nervous System (see page 149 of Manual for announcement of title).

On Wednesday A.M., February 7, one of the secretaries of the Section on General Hygiene and Demography read a paper written by Dr. ALVAH H. DORTY, of New York.

All the Sections met in various halls of the University.

Dr. FERD. C. VALENTINE, of New York, read his paper. (See page 52 of the Manual for abstract.)

Dr. JAMES S. FOOTE, of Omaha, Neb., read his paper. (See page 43 of the Manual for title.)

Dr. J. D. GRIFFITH, of Kansas City, Mo., read his paper. (See page 47 of the Manual for title.)

Dr. W. E. B. DAVIS, of Birmingham, Ala., read his paper. (See page 79 of the Manual for title.)

THE BADGE.—The badge worn by members of the Congress was of metal. The dimensions were between an American silver 25-cent piece and a half dollar, and about as thick, was silver-plated and contained on one side the Cuban coat of arms, which consisted of the rising sun over the sea between two points of land and a key below with the word Cuba thereon. The key—or Cuba by geographic position—is to indicate the honor, key to the Gulf of Mexico (or good position for naval and military power). At the bottom of the coat of arms is a palm on the right side, while on the left side our flag, the Stars and Stripes, is seen.

On the obverse side is the inscription, "Pan-American Medical Congress, Havana, 1901." Urn and serpent to indicate Science, and a laurel leaf. All of which was suspended from a yellow silk ribbon bow, indicative of the medical (physician's) color in Cuba.

Psychotherapy of Pain.—Oppenheim (*Therapie der Gegenwart*, March, 1900) believes that pain occurring in an extremity or circumscribed nerve area is often designated as neuralgia, while more frequently it is of a psychogenetic origin, due to neurasthenia, hysteria, or hypochondriasis. As these varieties of pain have, up to the present time, defied various therapeutic measures, it is worthy of mention that the author claims to have cured several cases by psychotherapeutic means. By systematic exercises he causes the patient to neglect the pain emanating from the affected area, in that the patient concentrates his or her entire attention upon some object like the ticking of a watch. If this fails, the patients are taught to direct their attention to two areas,—one near the seat of pain, the other at some distance from it. The author claims by these procedures to have established insensibility in the former painful areas. [M.R.D.]

11. Remarks on the Apparent Immunity of Asiatics from Enteric Fever. FRANCIS W. CLARK.

1.—Daniels believes that *Anopheles funestus* (Giles) is the chief agent in the distribution of malaria in East and Central Africa. After feeding 57 specimens of anopheles on a patient suffering from malaria whose blood contained crescents, 27, or 47.5%, were found to be infected. These 57 mosquitoes had fed 129 times on the patient and out of the 129 feedings, infection of the mosquitoes resulted in 46 instances, or 35.5%. Man appears to be the only intermediate host of the malaria parasites. From June, 1899, onwards the author made observations on the proportion of children of different ages with splenic enlargement, the absence of this condition in the adults having been previously noted. Out of 851 children under 15 years old examined 216 had enlarged spleens. A classification of these observations into a group under 2 years of age, a group between 2 and 4 years, and a group from 4 to 15 years, shows an earlier incidence and an earlier decrease in the proportion with enlarged spleens in the more malarious districts; and as chronic enlargement of the spleen does not always follow even repeated neglected infections, it also indicates a very high degree of prevalence of malaria in the natives in early life. The causation of enlarged spleen as a result of malaria is not well understood, and requires further investigation. This effect of malaria is in part dependent on race. No preventive method is or can be of general application to the exclusion of others. A combination of methods strictly in accordance with local conditions promises the best results. The outlook is hopeful, as a reduction in any factor by any one method will increase the effect of any other methods adopted. The greatest difficulty will result from the scepticism with which the subject will be met in the tropics. Sufficient regard to the species of anopheles has not yet been paid in describing their habits and breeding places. The very local distribution of some of the species indicates some important differences as yet unknown. It is requisite for each species of anopheles that direct proof should be obtained whether the human malaria parasites develop in them or not; in only a few is the proof at present conclusive, and it is being too hastily assumed that the whole genus is implicated. [J.M.S.]

2.—The paper is an exposition of the anatomy of the ova, larvae, and adults of *Anopheles maculipennis*. [J.M.S.]

3.—Van der Scheer and van Berlekom refer to a previously published report of an outbreak of malaria in Middleburg, the principal town in Zeeland, where for 30 years this disease had never occurred. There were two marked peculiarities of this epidemic: (1) It consisted only of cases of tertian fever, and (2) house epidemics were often observed. The malaria houses were reinspected this year with accuracy, and it turned out that several anopheles were found. It became evident that, as in Italy, anopheles prefer to live in stables with rab-

bite, horses, and other quadrupeds. Within such stables as were situated in the neighborhood of the infected houses whole colonies of them were found. The authors tried to infect anopheles by keeping them under a mosquito net, together with a person who suffered from malaria, and whose blood contained not only the so-called febrigenous parasites but also gametocytes, which are destined to undertake sexual functions in the mosquito's stomach and to form vermicules. Their experiments were immediately successful, so that, of 22 mosquitoes that had sucked blood containing gametes, one or another stage of development of the parasites was found in the bodies of 18. [J.M.S.]

4.—Thompstone and Bennett describe a disease that they call hyperpyrexial fever that is generally ushered in by a slight rise of temperature, followed by profuse perspiration and a fall in the temperature to about 99° F. After a period of apyrexia of perhaps 24 hours' duration, the temperature begins again to rise, slowly at first, but when 105° is passed with alarming rapidity so that 107° may be reached on the second day. For from 14 to 30 days subsequently there is absolutely no tendency for the temperature to fall. The skin acts either very slightly or not at all, and all antipyretic drugs fail. There is no enlargement of the liver or the spleen. The urine is of normal character and abundant; the bowels are regular or inclined to looseness. The mind remains remarkably clear in the majority of cases, except when the temperature is at its highest, but constant symptoms in the early days are great anxiety and restlessness. No plasmodia or pigmented leukocytes have ever been discovered, but in some of the latter cases it was noticed that the blood tended to coagulate the moment it was exposed to the air, so that it was only with great difficulty that satisfactory films could be obtained. Treatment of the condition is by baths. If the patient is to recover, some change for the better is to be looked for about the end of the third week. Convalescence is gradual, and it may be 6 weeks after the onset of the fever before the temperature finally assumes its normal course. On the other hand, in 50% of the cases that have come under observation a fatal issue has occurred. At the end of the second week, Annett found 4,384,000 red corpuscles, 15,000 white corpuscles, and 90% hemoglobin. Attempts to cultivate microorganisms from the blood failed. [J.M.S.]

5.—Hearsey gives summaries of 15 cases of hemoglobinuric fever, which he defines as an acute febrile disease, probably of malarial origin, and characterized by the occurrence of an extensive and rapid hemolysis. [J.M.S.]

6.—Smith uses the following method for the staining of flagella of microorganisms. A saturated solution of perchlorid of mercury, made by boiling, is poured, while still hot, into a bottle in which crystals of ammonia alum have been placed in quantity more than sufficient to saturate the fluid. The bottle is well shaken and the solution is allowed to cool. To 10 cc. of this fluid 10 cc. of a freshly made 10% solution of tannic acid are added and 5 cc. of carbol fuchsin. These are mixed and filtered. The cover-glasses are prepared by washing them in a strong solution of hydrochloric acid. They are taken from the acid, wiped with a clean cloth, and thoroughly heated over a Bunsen flame. On a cover-glass which has been sufficiently heated, the film spreads with perfect evenness. The traces of acid that are left on the glass make it easier to avoid subsequent precipitation of mordant or stain. The bacilli are placed on the cover-slip and fixed. The mordant is then filtered, poured on the preparation, and heated till steam is given off. Boiling should be avoided, as it leads to precipitation. The preparation should be kept at this temperature for 3 minutes. It is then well washed in distilled water, and the stain is added and heated in the same way for 3 or 4 minutes. The stain is made by adding 1 cc. of a saturated alcoholic solution of gentian violet to 10 cc. of a saturated solution of ammonia alum. This is filtered and poured on the preparation. This method is particularly applicable to bacilli of the typhoid and colon group. The flagella of the cholera bacillus, the tetanus bacillus, and the vibrio aquatilis are well stained by this method. [J.M.S.]

7.—Lustig and Galeotti in their studies on the treatment of plague determined to inoculate, as a preventive medium, the substance that is alone able to cause in the organism treated an active immunity produced by the action of a specific bactericidal power. This substance was obtained by isolating from the microorganisms the nucleoproteid of

which they are partly composed, for it is to this that immunity is due, although it can be also produced by injecting entire cultures of plague microorganisms. Through the injection of this nucleoprotein, which is an intracellular specific poison, the authors were able to confer on the serum of the animals a bactericidal power, and very likely an antitoxic one as well. The first serum was obtained in the year 1897 and was tried in India on 6 patients, 5 of whom recovered. Besides 29 patients were treated with it in the Poona Plague Hospital, and 21 of them got well. The number of patients treated with this serum on June 10 was 175. The results were altogether very satisfactory, but a great difference in the serums coming from different horses was noted. The mortality among the patients treated with the serum may be placed at about 53%, while the general mortality for plague at the same period was, according to the official statistics, about 94%. More recent results of the treatment of plague with this serum have been published in Dr. Polverini's report. The rate of recovery was 39.36%. At the Arthur Road Hospital, 1,190 patients were treated without serum during the same period with a mortality rate of 19.57%. [J.M.S.]

8.—Much of the dysentery which the private soldier in South Africa believes he suffers from is not dysentery. It usually resolves itself, on questioning the patient, into diarrhea, accompanied by griping pain. In the advance through the Free State one saw many cases of acute diarrhea, in a large percentage of which blood and mucus were passed. Very few of these ended as acute dysentery. The few cases of real dysentery occurring in Colville's Division improved rapidly under treatment with magnesium sulphate, given in hourly doses of 1 dram, and dieting. Out of some hundreds of cases of acute diarrhea and dysentery treated, Day only saw 1 death occur actually in the field, and that was a case of long duration. On admission, the patient was immediately given castor-oil, 1 ounce; tincture of opium, 15 to 25 minims; peppermint-water, 1 ounce; and a diet of arrowroot, milk, soda-water, and brandy or portwine. As soon as the bowels had been thoroughly cleared, magnesium sulphate, 1 dram; dilute sulphuric acid, 15 minims; and peppermint-water, 1 dram, was given every hour until the stools became feculent. As the tenesmus was relieved and the evacuation of blood and mucus ceased, the sulfate of magnesium was administered correspondingly less frequently, but was always continued for about 48 hours after the dysenteric symptoms had ceased. Several cases were complicated by scurvy, malaria, and synovitis. There is a great tendency to relapse should the patient be allowed to get about in the sun too soon during convalescence. Cases of dysentery should be kept separate from cases of typhoid fever. As much care should be taken to either disinfect or destroy the stools of dysentery patients as of patients suffering from typhoid. [J.M.S.]

9.—At the postmortem examination of an adult male who had died from chronic cirrhotic disease of the liver and kidneys Ruffer noticed the *oxyuris vermicularis* in great numbers in the contents of the large intestine, more especially in its lower portion. In the rectum, about 6 inches from the anus, 3 small hard tumors were found, that lay within the walls of the intestine, and was of the size of a small nut, while here and there throughout the length of the large intestine small elevations were also noticed. These varied in size from that of a pin's head to that of a small pea. The mucous membrane covering these tumors and the elevations above noticed was quite intact, and there was no sign of congestion, inflammation, or ulceration around the tumors. Each of these tumors contained a calculus; it shelled out quite easily from the surrounding connective tissue, which formed a capsule around it. The mucous membrane and the submucosa formed the anterior wall of the cyst, the posterior wall consisting of the muscular layer and peritoneum, a thick capsule of connective tissue surrounding the calculi. These calculi were rough, uneven, but not so hard that they could not be cut with a strong scalpel. They were mainly of a yellowish black color, but almost white in parts. The addition of a small drop of mineral acid to a fragment at once produced a strong evolution of gas. Microscopic examination of any one of these calculi showed that they consisted of an amorphous yellowish brown substance, which contained numberless typical eggs of *oxyuris vermicularis*. No traces of the worms themselves could be found inside the cyst. The only possible explanation of these facts is that the *oxyuris* penetrated through the mucous membrane into the

wall of the intestine, and there laid its eggs. These acting as an irritant produced a certain amount of inflammation followed by calcification. The female either found her way back into the intestine, or died and was absorbed. It is quite possible that this process takes place frequently. [J.M.S.]

10.—Prout examined a rounded tumor, about the size of a pigeon's egg, that was removed from the buttock of a frontier policeman, who complained of vague rheumatic pains. In appearance and consistency the tumor resembled a fatty tumor, but, on excising it, it was found to be a cyst containing what seemed to be a mass of filariae bathed in a semipurulent fluid. Later a similar tumor was removed from another frontier policeman. On making an incision into this mass, a greenish, semipurulent looking fluid about the consistency of cream escaped from the cyst. This, on microscopic examination, was found to contain numerous filarial embryos. The interior of the cyst was filled with the adult filariae lying in loops twisted up in the most convoluted fashion, entering the cyst wall, running along shallow tunnels, and reentering the cyst. Owing to this and the softness and brittleness of the worm it was a matter of the greatest difficulty to dissect it out, and it was found impossible to do so without breaking it. Eventually, however, the author succeeded in isolating a complete unbroken adult male, and the head, tail, and intermediate fragments of a female. These two worms formed the whole contents of the cyst. The worm is considered to be a specimen of *filaria volvulus* (Leuckhart). [J.M.S.]

11.—During 10 years only 51 deaths of Chinese from typhoid fever were registered in Hong Kong, as against 65 deaths of non-Chinese, although the Chinese form 94% of the total population. Clark believes, and so stated in a former report, that the Chinese are so fully exposed to the infection throughout the whole period of their existence that they almost always contract the disease in infancy or early childhood, when, if they recover, the disease will have been practically unnoticed, while, if they succumb, the death will be attributed to diarrhea, convulsions, or some other symptom. Should they happen to contract a second attack in adult life, it will be so modified by the previous one as to be again scarcely recognizable, or at least to be insufficient to drive the patient to a hospital under European control. During the current year, while 12 deaths have been registered as due to this disease among the non-Chinese, 22 have been registered among the Chinese, and of these 7 were in infants under 1 year of age, and one a child between the ages of 1 and 5 years. It must be borne in mind that these cases have, moreover, been found amongst the few bodies of infants that are picked up in the streets by the police, and that no postmortem examination is made of the bodies of the 1,500 or more infants that are taken annually to the French and Italian convents in a moribund condition, and whose deaths are registered as due either to diarrhea, undefined fever, marasmus, or convulsions, and that these convent returns comprise about 75% of the total deaths in the colony under 5 years of age. It would seem that the immunity of Asiatics to typhoid fever is only an apparent one. [J.M.S.]

1.—Mott delivered an address before the Nottingham Society on October 10, 1900, on "The Selective Influence of Poisons in Relation to Diseases of the Nervous System." He points out the important fact that each nerve-cell, unit or neuron possesses a biochemical sensitiveness or chemiotaxis, which is influenced by its lymph-environment. The failure of the neuron to carry out properly assimilation and dissimulation owing to improper environment and inherent qualities is the essential which governs functional diseases and primary degeneration of the nervous system. Secondary diseases of the nervous system are due to such causes as hemorrhage, thrombosis, embolism, tumors, injury and diseases of the neuroglia and membranes. In his address he refers only to primary intoxications and degenerations. While toxic substances circulating in the blood or lymph come in contact with all the nervous tissue equally, still certain nerve elements are especially susceptible to some poisons and it is through the particular symptoms which manifest themselves that the poison is often recognized. He mentions as striking examples, tetanus and rabies. Toxic substances often act as predisposing or exciting causes in individuals who show an hereditary neuropathic tendency or who are subject to excessive activity or stress. Mott, therefore, points out as cardinal factors in the causation in the majority of cases, toxemia, stress, and hereditary neurosis. Largely through the nervous system of the individual are the internal activities and the relation to his surrounding environments maintained. He states that the important property of the nerve unit is excitability, and that poisons may increase or diminish this function. Nature guards against the entrance of many poisons into the alimentary and respiratory tracts by the sense of taste and smell. Poisons in the circulation are often neutralized by the secretions of antitoxin. In some instances the nervous system shows a gradual tolerance to toxic environment (habit poisoning), a condition after once established is often indispensable to proper functional activity, and a rapid withdrawal of such toxic surroundings would bring about abnormal activity of the nervous system. He clearly states that every nerve unit possesses potential energy which when called upon may be transferred into active energy. He further adds that potential energy is maintained through the proper relation of constructive and destructive metabolism, and upon the activity of the protoplasm. In neurasthenia potential energy is reduced. There is also a relation existing between certain nerve groups. A paralysis of one group may cause overaction in another unopposed group. In this way many symptoms of nervous diseases are brought about. He divides the toxic substances in the blood or lymph which cause increase or decrease excitability of the nerve elements into those that are introduced from without (exogenetic) and those that are produced within the body (autogenetic). He calls particular attention to such poisons as alcohol, opium, hashish, morphia, cocaine, tobacco, and absinthe; each causing specific action on the higher mental functions, however, always modified by individual temperament. He believes that different toxic substances act upon certain projection fields or identification centers of the brain. He refers to the effects produced by hashish, which consist of remarkable illusions relating to the notion of time and space. Also to the effect produced by morphia, causing persistent and uncontrollable ideation. He states that alcohol is directly or indirectly responsible for 20% of the mental and nervous diseases of the inmates of the London County Asylums. He refers to chronic alcoholism as causing dementia. The characteristic mental symptoms of this chronic intoxication are personal illusions, absence of the knowledge of time, space and loss of memory, especially for recent events. In many of the alcoholic cases, peripheral neuritis was associated. To tobacco is attributed a special action upon the neurons of central vision causing amblyopia, and to lead poisoning is attributed the selective action upon the nerves which supply the extensor muscles of the forearm, producing wrist-drop, and also an action on the brain (encephalitic saturninia). The affection known as pellegra is characterized by degenerative changes in the spinal cord and in the brain and by cutaneous lesions. The special action upon the nervous system produced by ergot poisoning is also mentioned. Under 2 headings he then considers the poisons elaborated within the body; (1) from perverted functions of organs or tissues, and (2) by microorganisms. Under the first group he

calls attention to the nervous derangements due to uremia, to exophthalmic goiter, to toxic substances formed and absorbed during digestion, to cholemia, to diabetes and to pernicious anemia. Under the second group he mentions that delirium occurs in many of the acute infectious diseases, and also that the peculiar selective action of the toxin of rabies and tetanus is striking. When tetanus toxin is mixed with an emulsion of nervous matter it loses its poisonous properties. He further refers to the neurotoxin of diphtheria and the depressive action upon the nervous system produced by influenza. Finally he calls attention to the virus of syphilis as being responsible for many nervous diseases, particularly locomotor ataxy and general paralysis of the insane. He cites the Argyll-Robertson pupil as being an example of the selective action produced by the virus of syphilis. The few manifestations of syphilitic infection in married women who give birth to syphilitic children, he believes is to be explained upon the ground of spermatic infection of the ovum from the syphilized father and that the gradual absorption of toxin from the fetus by the mother renders her immune. [F. J. K.]

2.—Atkinson, in a lecture on **plague**, calls attention to the sudden onset of the disease, marked by chill, fever, great prostration, intense pain in the region where the bubo appears, and occasionally delirium. These early symptoms are soon followed by headache, thirst, vomiting, diarrhea, and depression. The tongue is swollen and coated, the skin is dry, and the conjunctivae are injected. During the first 5 days the buboes appear; the temperature-range is high during the first stage, which lasts from 6 to 10 days. It then falls to normal and, with suppuration, there is a secondary rise. Carbuncular affections and petechia are common. Buboes are of large size in 73% of the cases, and small in the remaining 27%. In 90% suppuration develops. The groin, axilla, neck, and the submaxillary region are the most common seats for the buboes. The most important symptoms referable to the digestive tract are loss of appetite, vomiting, and diarrhea. The tongue is dry and coated, there are no important respiratory symptoms in the bubonic variety. The heart shows the signs of a myocarditis, and in 95% of the cases in the epidemic of 1896 albumin was found in the urine. Sleeplessness, muscular twitchings, deafness and delirium and coma are common nervous symptoms. He states that amongst the Chinese the mortality is 90%. The mortality of those treated in hospitals varies from 73% to 88%. In the Europeans it was between 40% and 50%. Early in an epidemic the death-rate is higher than towards the close. The important pathological changes are swelling and suppuration in and about many of the superficial lymphatic glands, hemorrhages into the skin and other parts of the body, enlargement of the spleen and inflammatory changes in the cerebro-spinal membranes, kidneys, liver and heart. He mentions 3 varieties of the disease: (1) The bubonic, which is the most common form and comprises about 70% of all cases. In this variety the infection is through the skin; (2) the pneumonic, a more fatal form and occurs without external buboes. The portal of infection being through the respiratory tract; (3) the gastrointestinal variety which is also very fatal. He states that the bacillus has been found in great numbers in the buboes and spleen, and also in the lymphatic gland, heart, lungs, liver, kidneys, walls of the stomach, in the feces, vomit, saliva, urine and in the blood. The microorganism has ever been found in the blood corpuscle. He gives the size of the bacillus as 1μ in length and 3μ in breadth. It decolorizes by Gram's method, and stains with the ordinary basic anilin dyes. In the stained preparation it shows the characteristic polar appearance. The bacillus is motile and is best cultivated at a temperature of 37°C , but it will grow at a temperature as low as 23°C . The diplococcus of pneumonia and the streptococcus will not thrive at a low temperature, so that this fact is of value in the isolation of the *Bacillus pestis* from the sputum. The microscopical examination of the blood in 276 cases showed the presence of the plague bacillus in 221 instances. If the microorganism is not found by microscopical examination of the blood, inoculation experiments into susceptible animals and upon artificial culture media should be tried. The diagnosis of plague is a rule easy. It is differentiated from enteric fever, particularly by a sudden onset. Typhus fever runs a shorter course. The disease is spread by means of the con-

taminated discharges from the patient and is carried by such animals as mice, rats and pigs. It is not probable that the bacillus is conveyed through the air, as sunlight in a very short while kills the microorganism. The germ may gain entrance into the body through the skin, the respiratory tract and the gastrointestinal tract. In order to prevent the extension of the disease strict hygienic regulations should be enforced by medical health officers and inspectors of the local government boards. Any person coming in contact with a person affected by this disease should be placed in quarantine for at least 10 days. Careful disinfection and the burning of the dejecta should be strictly enforced. All meat should be inspected. All rats should be destroyed, as they seem to carry the infection. The methods of personal hygiene should also be rigidly followed, especially the care of the skin. Food should be well cooked and the water boiled. He concludes his article by giving the measures adopted in Hong Kong for checking the disease. [F.J.K.]

3.—Parkes and Rideal suggest a method of preventing **water-borne enteric fever** amongst armies in the field by means of weak solutions of sodium bisulphate which are to be used as drinking water. After a number of experiments with different substances, the authors conclude that sodium bisulphate is best suited for the purpose, and they recommend a tabloid of 5 grains to be placed in a cupful of water. The solution should be allowed to stand for 15 minutes before drinking. The acid tabloids render the water more palatable and aid in slaking thirst. Three hundred and fifty tabloids weigh about a quarter of a pound, and these are sufficient to sterilize over 100 pints of water. These tabloids may also be used as thirst lozenges. [F.J.K.]

4.—Parker discusses acquired syphilis of the nose and pharynx. He states that primary syphilis of the nose is very rare. The common seat of the primary sore is generally on the ala or just within the vestibule. The manifestations of secondary syphilis of the nose are coryza, mucous patches, rhinitis erythematosa, and rhinitis papulosa and superficial ulceration. Tertiary manifestations of the nose are quite common. They are gummata, superficial ulceration, deep ulceration and necrosis, and scars and deformity. The complications of tertiary syphilis of the nose are catarrhal otitis, purulent otitis, deafness, pharyngitis, and laryngitis sicca, perforation of the hard palate, and cerebral diseases. He then mentions the diagnosis of syphilis of the nose and outlines the treatment. He states that primary syphilis of the pharynx is fairly common and the most frequent seat being upon the tonsil. He mentions that Seifert collected 179 cases of chancre of the pharynx. He states that the manifestations of the secondary syphilis of the pharynx are erythema, mucous patches, and superficial ulceration, and that the tertiary lesions are gummata, ulcerations, scars, and deformities. In discussing the treatment of syphilis of the nose and pharynx he states that mercury should be given in the primary and secondary stages of the disease, and that a combination of iodid of potassium and mercury gives the best results in the tertiary stage. [F.J.K.]

5.—Milton reports a very interesting operation for the removal of a **foreign body** lodged in the **right bronchus**. The patient, a man, 40 years of age, had some years previously had a tracheotomy done for syphilitic stenosis of the larynx, since when he had always worn a tube. A short time before admission the inner portion of the tube became detached and passed down the trachea. The tube could be felt with a probe through the tracheotomy wound, but could not be seen. Several unsuccessful attempts were made to remove the tube with hooks, forceps, coin-catchers, etc. It was finally determined that the only way to remove the tube was by means of a thoracic section. Milton had on a previous occasion removed a tubercular tumor from the anterior mediastinum, and determined to approach the bronchus in the same manner. An incision was made from the tracheotomy wound to the ensiform cartilage. The sternum was divided with a saw, after separation of the tissues beneath it with the finger, and the edges forcibly separated with strong retractors. An incision 2 cm. long was made in the anterior wall of the trachea, just above the bifurcation. This was followed by a flow of bad-smelling, frothy mucus. The tube had caused considerable ulceration of the bronchus, but was removed without much difficulty. There was little hemorrhage and no interference with circulation and respiration. The bronchial wound was closed with considerable difficulty,

and a gauze drain allowed to pass from it through the wound in the sternum. Excepting for the point of drainage, the external wound was closed throughout. The split sternum was not sutured. The patient suffered no shock during or after the operation. For the first 24 hours the patient was entirely comfortable, but there was some rise of temperature. The gauze drain was removed with considerable difficulty, and was followed by a flow of fetid fluid. There were present moist rales in both lungs, and respiration was increased in frequency. The patient died on the third day, temperature 102, apparently from heart-failure. Postmortem examination showed anterior mediastinum to be the seat of an acute septic condition, and both lungs showed a beginning pneumonia. The pericardium, pleura, and great vessels showed no lesion. There were two pressure-ulcers of the right bronchus. Milton thinks that death was due to acute septicemia. In discussing the case he says that he thinks that the closure of the bronchial wound was a mistake, and that if performing the operation again he would leave an opening through the body of the sternum for the purpose of drainage, and close the slit in the rest of the bone with silver sutures. He remarks on the absence of shock in both of his cases. He thinks there is little risk of hemorrhage when an ordinary amount of care is taken. He thinks the only real danger in the operation is sepsis. Where asepsis can be absolutely assured, complete immediate closure of the thorax would be indicated. Drainage can be accomplished through the sternum, upwards through the neck, or backwards through the middle and posterior mediastinum. The backward drainage is not as difficult as it seems at first sight. Although the method of drainage must vary with each case, Milton thinks the anterior route through the sternum to be the best. [J.H.G.]

6.—Fisher reports a case of **extensive deposit of phosphate of lime in the lungs**. The patient, 32 years of age, was admitted into the Bristol Royal Infirmary suffering from pneumonia, and died upon the day of admission. The autopsy revealed complete consolidation of the right lung and partial consolidation of the lower left lung. The pneumonia was in the stage of red hepatization. Scattered throughout the right and the left lung were numerous granules about the size of grains of sand. These small masses were very dense. A chemical examination of these bodies showed that they were made up of 75% of phosphate of lime. Microscopical examination showed that they were situated in the walls of the alveoli and that they were composed of concentric layers. The nodules were not connected with any of the surrounding bloodvessels. The authors conclude that these bodies were due to amyloid deposits with secondary infiltration of phosphate of lime. [F.J.K.]

7.—Douthwaite reports a case of **poisoning by coal-tar naphtha** in a girl 5 years of age. Between 2 and 3 ounces of the liquid were taken. Shortly after the ingestion of the poison the patient was in an almost complete comatose condition, the respirations were hurried, there was a heavy benzine-like odor to the breath, the face was somewhat livid, the skin cold and clammy, the pupils were dilated, and the pulse was rapid and feeble. The treatment consisted in the use of artificial respiration, hypodermic injection of brandy and the administration of common salt as an emetic. The patient finally recovered from the poisoning, but succumbed to an acute attack of bronchitis some days after. [F.J.K.]

8.—A case of **anthrax** is reported by Kidd in a man 27 years of age. The infection was probably conveyed through the handling of hides. The lesion was situated on the neck and followed a crop of boils. The clinical manifestations of anthrax infection were very well marked, although a bacteriological examination was not made. The local treatment consisted in making free incision into the inflammatory area. He states that the patient passed through a severe illness and finally made a good recovery. [F.J.K.]

9.—Heaton reports a **remarkable tolerance for arsenic** in a case of splenomedullary leukemia. The drug was administered in the form of arsenious acid and arseniate of soda. During a period of 271 days, including intermissions of 58 days, 5½ grains of arsenious acid and 105 grains of arseniate of soda were administered hypodermically. For a while the treatment had a beneficial effect upon the blood. [F.J.K.]

10.—Blake gives a report of 35 prophylactic injections of antidiaphtheritic serum. These prophylactic measures were

instituted after 3 cases of diphtheria developed in the Sun-trap Convalescent Children's Home, High Beach, Essex, Eng-land. The cases of diphtheria were immediately isolated and the remaining 35 children were treated with the prophylactic injections. No other cases of diphtheria developed. [F.J.K.]

8. Tracheal Injections in the Treatment of Pulmonary Tuberculosis. T. MORRIS MURRAY.

1.—Charles Phelps reports a case of **gastrointestinal hemorrhage** caused by fatty degeneration of the right ventricle of the heart. The patient, a man of 58 years, had accumulated much abdominal adipose tissue and had acquired a small umbilical hernia. He had suffered from no other ailment than gout and indigestion. The operation upon the hernia was simple and without incident save that the anesthetics were badly borne. His general condition following the operation was poor, and on the afternoon of the fourth day he died, soon after a large, gastric hemorrhage. Postmortem: The liver was found to be slightly enlarged with considerable fatty infiltration. There was a less decided cortical atrophy due to chronic passive digestion. Endoarteritis of the small branches of the hepatic artery was found. There was also a moderate degree of chronic interstitial nephritis. The lungs were small and nearly bloodless, but otherwise of normal appearance. The heart was of normal size, its right ventricle was covered with a layer of fat, at least $\frac{1}{2}$ inch in thickness, and the wall of this ventricle was thin as paper, and almost pultaceous in character. The left side of the heart was less encumbered by fatty deposits and it suffered less fatty degeneration of its fiber. The cirrhotic disease of the liver had not advanced sufficiently to account for the fatal gastrointestinal hemorrhage, but the condition of the heart seemed to afford explanation. The blood accumulated in the right side of the heart, and, secondarily, in the inferior vena cava and portal system until the overdistended gastrointestinal vessels finally gave way. [T.L.C.]

2.—Leon L. Solomon presents a **clinical analysis of digitalis and its preparations**, calling especial attention to the **glucosides** and more especially to **digitoxin**. Digitoxin has been especially recommended in chronic myocarditis and in cases of ruptured compensation. He recommends a solution of digitoxin to which a little chloroform is added to prevent its precipitation and has found the following combination to be of great service. Digitoxin $\frac{1}{10}$ grain, chloroform $1\frac{1}{2}$ minims, and alcohol (at 90%) 23 minims. Water sufficient to make half an ounce. [T.L.C.]

4.—Jelks reports 24 cases of **autointoxication from renal insufficiency**, with and without diseased kidneys. The patients suffering from renal insufficiency die, usually, not from the nephritis but from the cardiac complications. Hence, the main indications for treatment are connected with the heart. Conditions of high tension and overaction should be met with nitroglycerin, opium, chloral hydrate or iodide of sodium. If dilatation of the heart is threatened, digitalis infusion or digitalin should be prescribed with rest in bed. In using digitalin, Jelks prefers the German Merck digitalin in preference to the American or French. He administers this

remedy in doses from $\frac{1}{15}$ of a grain to $\frac{1}{2}$ of a grain 3 or 4 times a day. [T.L.C.]

5.—Hering first discusses the various sites of intestinal obstruction and the causes of this condition. In his experience chronic constipation with fecal impaction is the most common cause. The most frequent site of the impaction is the descending colon. The symptoms of intestinal obstruction are next enumerated and discussed. Prophylaxis is best accomplished by preventing or overcoming constipation. For this purpose he not only recommends medicine and diet, but particularly massage and exercise. The **operative treatment** should be instituted promptly if the use of high enemas has proved unsuccessful. The administration of purgatives, particularly in cases of intussusception, is questionable treatment. The various methods of intestinal and anastomosis are then dealt with. After operation measures to move the bowel are not to be instituted until the third day. [J.H.G.]

6.—Horsley reports a very typical case of meningeal hemorrhage in which operation gave immediate relief. The patient was a man 22 years of age, who was struck on the head with a wooden club. He was unconscious for a short time after the injury, but regained consciousness and felt perfectly well until several hours later, when he again became unconscious, developing complete hemiplegia. Twenty-four hours after the injury Horeley removed a large epidural clot and instituted drainage. The next day the patient was conscious and had an uninterrupted convalescence. [J.H.G.]

7.—Lilienthal, after discussing infection of wounds from skin sutures, recommends a method of wound closure which he has employed in hospital and private practice with uniform success for 3 years. The deeper portions of the wound are closed with subcutaneous sutures and the skin is then brought together by means of narrow strips of sterilized zinc-rubber plaster. This method has resulted in aseptic healing in all wounds and gives a resulting scar such as follows the use of the subcuticular suture without any of the drawbacks of the latter. [J.H.G.]

8.—Murray recommends an **intratracheal injection** composed of essence of thyme, essence of eucalyptus, essence of cinnamon, of each 5 grams; sterilized olive oil, 100 ccm. This is the solution recommended by Mundell, of Roubaix. Murray's results have confirmed Mundell's to some extent. He injects 3 ccm. 3 or 4 times consecutively. The method of administering intratracheal injection is simple. The curved canula of the syringe is passed between the vocal cords and the fluid is slowly injected into the trachea. He employs the Schadel syringe. The usual effect, in a majority of the cases, is a slight explosive cough. He has not observed a single instance of glottic spasm follow even the first injection. Out of 13 cases treated during the past 7 months, 10 have been benefited decidedly, the cough and expectoration had been lessened and the temperature lowered. This improvement is the more noteworthy because the patients were very poor, not in the hospital, and were under the most unfavorable surroundings. [T.L.C.]

1. Summary of the Progress Made in the Nineteenth Century in the Study of the Propagation of Yellow Fever. CHARLES FINLAY.
2. Investigations upon Corporeal Specific Gravity, and upon the Value of this Factor in Physical Diagnosis. HEINRICH STERN.
3. The Use of the Aqueous Extract of the Suprarenal Capsule as a Hemostatic. W. H. BATES.
4. The Clinical Significance of Dulness in Appendicitis. H. T. MILLER.

1.—Will be treated editorially.

2.—Stern reports the result of a series of investigations on **corporeal specific gravity** and upon the value of this factor in **physical diagnosis**. The determination of the absolute weight of an individual is an important factor to the physician and medical examiner in general. Frequently, however, the absolute body weight does not reflect the real physical condition of the organism. This is especially important in recognition of the fact that light or heavy

people need not necessarily be afflicted with a wasting disease or with obesity. The specific weight of an individual and the density of his structures have been assigned too insignificant a role in medical diagnosis and therapy. It is the density of the organism and its tissues and not its absolute weight which discloses with an almost absolute degree of certainty its soundness as well as a variety of morbid conditions. Stern describes his method for the determination of the corporeal specific gravity for which the reader is referred to his paper. The tabulated results of the specific gravity of certain parts of the body are given. The writer concludes that after the second week of life, the density which is highest (1.066) soon after birth declines to 1.048 in boys and 1.050 in girls, to remain at this minimum until the close of the second year. Thereafter a slow but steady rise sets in, which culminates in the male between the twenty-fifth and forty-fifth year, and in the female after the menopause. In the advanced period of life, the blood density in both sexes is raised once more, it thus contains towards the close of life a similar degree of concentration as at the time of birth. The information furnished by the body density of an individual will assist us in determining certain questions. Among these are: Body soundness, body immunity, and probable duration of life. [T.L.C.]

3.—W. H. Bates, of New York, emphasizes some facts as to the value of **suprarenal substance as a hemostatic**. He believes after 6 years' experience in its employment that it is the most powerful known astringent and hemostatic. Satisfactory results will be obtained with a freshly prepared mixture of one part of the dried and powdered gland, and 10 parts of water. For the use in the eye or ear the emulsion should be filtered. Sterilization by heat will not alter its efficiency. The mixture when used locally will always control hemorrhage from mucous membranes. The internal use of the extract as a hemostatic is efficient in some cases. Another important factor is that suprarenal extract when it controls hemorrhage locally, or after internal administration, does so in less than one minute. [T.L.C.]

4.—H. T. Miller believes that sufficient stress has not been placed upon the **point of dullness in appendicitis**. In every instance in his experience in which he has relied upon this symptom he has been led to a correct conclusion. In cases without any pronounced inflammatory symptoms, and in which the dullness was marked, he found the appendix indurated and adherent to the adjacent tissue. Nineteen cases are briefly reported. In every instance in which dullness was present, pus was diagnosed, and this was verified either by operation, or by autopsy, with the exception of 2 cases of his series. [T.L.C.]

5. A Report of some Cases of Abdominal Surgery, with Remarks on the Diagnosis of Carcinoma of the Cecum and the Surgical Treatment of Carcinoma of the Liver and the Gallbladder. CHARLES GREENE CUMSTON.

1.—DeLancey Rochester presents a clinical report of six unusual cases. The first, in which a child had a slight rhinitis with a pulse of 80 and a temperature of 100°. He was also suffering from a sore throat which had come on about midnight of the day before. Rochester makes a practice of taking cultures of sore throat, and did so in this case as a routine matter. A report was received that a pure culture of the *Klebs-Löffler bacillus* was found. Antitoxin was at once administered, although there was no exudate visible, and the constitutional disturbance was not great. Twelve hours after the antitoxin was given he discharged two pieces of membrane from his nose. Twenty-four hours later he appeared better, but 36 hours afterward both tonsils of the

pharynx were covered with **membranous exudate**, and there was a rise of temperature to 101.5°. His second case was somewhat similar in the throat symptoms and the bacteriologic report. However, in this case a **croupous pneumonia** developed, and **pneumococci** were found in the sputum in pure culture. Antitoxin was administered in this case early and in large doses. These two cases are interesting as showing the value of making pure cultures from all cases of sore throat. The second, particularly, illustrates the importance of using all methods of diagnosis, and the possibility of **synchronous infection with two virulent microorganisms**. Had it not been for the discovery of the pneumococcus the second case might have been regarded as a pneumonia of **diphtheritic origin**. His last three cases are those of **scarlatina without eruption**. In Case 3 the child had come home from school sick, had vomited and was complaining of headache. His temperature was 102.5°, his pulse 120, respiration 28. There was a marked **bronchitis** and a few patches of **pneumonic involvement** at the base of both lungs. Calomel was ordered, the chest was cupped, and hot foot-baths given every two hours. The next morning the nurse called attention to the fact that during the foot-baths the child became very red, but when seen there was no rash on the body and the tongue and throat showed no evidences of scarlet fever. In 5 days the child had completely recovered. In Cases 4 and 5 the patients were two little brothers with very slight febrile symptoms, their throats were not sore, but there was a peculiar mottling of the skin, and they both had vomited. Eighteen days after the first child was taken sick, both he and his brother appeared well and were vaccinated. The writer noticed at this time that his fingers were desquamating a little, and the diagnosis of **scarlet fever** was made. This doubt was settled by an older brother being taken ill in a few days with a frank case of **scarlet fever**. His sixth case suffered from **two attacks of scarlet fever**; the second occurring late in the period of desquamation of the first attack. Several physicians saw the child during both periods of eruption. [T.L.C.]

2.—According to Moschcowitz every **amputation-stump** should respond to the following requirements: 1. It must be able to support the weight of the body. 2. It must be painless. 3. It must be no more liable to local disease than any other portion of the body. 4. It must disfigure its owner, as is commensurate with the nature of the ailment. He then describes the technic of amputation of the leg which he uses as a prototype, all the amputations being merely slight modifications, which can be readily adapted to the special limbs to be amputated. [W.A.N.D.]

4.—Edward Adams, of New York, concludes that the chief advantages of the M. S. mixture (the combination of ether and chloroform) are the following: 1. The stage of excitement and struggling are not marked. 2. It requires a short time to get a patient under,—5 or 10 minutes. 3. Very little of the anesthetic is required—on an average about 40 cc. are used an hour. 4. It is a comparatively safe anesthetic. 5. It is very pleasant to take. 6. The after-effects are not marked. 7. Patients recover quickly. 8. It can be used in nearly every condition in which either chloroform or ether is employed. [T.L.C.]

5.—Cumston gives a "potpourri" of various surgical cases, illustrating **abdominal conditions**, especially those connected with the cecum, liver, and gallbladder. He gives illustrative cases in this the first portion of the paper, which is to be concluded in the subsequent number of the journal. [W.A.N.D.]

7. Gonorrheal Prostatitis. JOHN BAPTIST BLAKE.
8. Gonorrheal Conjunctivitis. CHARLES H. WILLIAMS.
9. When is a Gonorrhea Cured? PAUL THORNDIKE.

1.—Tenney endorses Guiard's conclusion that every case of urethritis that lasts more than a few days is, or at least may have been at the start, a true infection by the gonococcus. That mild and transient inflammations of the urethra with purulent discharge do occur in the course of acute fevers, attacks of gout or articular rheumatism, and are acquired from instruments or from sexual contact, must be admitted. The growth of the organism may be divided into 3 stages: 1. On and in the epithelial cells. 2. In the sub-epithelial layer and the leukocytes, where they develop very rapidly. 3. In the epithelial cells again, as the growth of a sort of dam of new tissue beneath them furnishes a layer unfavorable to the development of the gonococci. The persistence of the infection is a matter of great importance, and also a matter in which the greatest care in diagnosis is necessary. In the declining stage, when pus cells must be found on the threads or by sedimentation, the greatest accuracy in staining by Gram's method is essential. While we know that this germ in some individuals will reproduce itself for months and even years in some pocket of the urethra, prostate, or seminal vesicle, it usually disappears within from 3 to 5 months. That sterility may, and often does, result from a gonorrheal infection, is a simple and reasonable proposition, but sterile marriages are not necessarily sterile because the wife has been infected by the husband. The latter may have become incapable of impregnating by the obliteration of his seminal canals, and then have starved out his gonococci, before marriage. The author does not believe that infection of a wife by a husband who has had no visible discharge for months is at all a common event. Nevertheless, it undoubtedly has occurred in some cases, and it is a part of the duty of the doctor who treats men with this disease to have a square talk with every patient, and fully explain why he ought to make sure by as competent examination as he can get that he is completely free of his gonococci before he marries, no matter when that may be. He refers to the work of Christmas, who cultivated gonococci and thus produced a poison that would kill a guinea-pig in from 5 to 7 hours. From this toxin an antitoxin was produced. As the damage and discomfort to the ordinary individual appear to be due more to the marvelous fertility of the organism than to its toxin-producing power, one would think the usefulness of an antigonotoxin would be limited to the complications of gonorrhea that are accompanied by constitutional symptoms. The author is of the opinion that about 20% of the males and 5% of the females of the community may have become infected at some time, but certainly no more. The common impression is that no immunity follows an attack of gonorrhea. Judassohn, however, introduced pus from a fresh gonorrhea into 6 urethrae that were in the chronic stage of gonorrhea, and of these 2 only started afresh. Without question gonorrhea resembles other bacterial diseases in the resistance offered by different individuals to its progress and even to its onset. In the majority of cases the gonococci probably are confined to the urethral tissues, while in others they escape by the blood- or lymph-channels to find lodgment in some joint or tendon-sheath or even in the heart. It seems a reasonable proposition that the same conditions that favor the persistence of the disease and stimulate the pathologic process should also favor the infection. The chief conditions that are recognized as having this power are the use of even moderate amounts of alcohol, sexual excitement, a tendency to gout or rheumatism, and tuberculosis. While Tenney does not maintain that alcohol is the only reason for the usual human susceptibility to this organism, he does believe that it has an influence that is too little recognized at present [J.M.S.]

2.—The important diagnostic point for the gonococcus is its property of decolorizing by Gram's method. The other points of morphology and position inside the leukocytes, are not necessarily characteristic. In the bacteriologic diagnosis of urethral inflammation the most important precautions are: (1) To smear the pus on the cover-glass in a thin film; and (2) to see that the anilin oil gentian-violet solution has not decomposed. In order to avoid errors in this regard, the solution should not be more than 2 weeks old. From the so-called scientific standpoint Richardson does not consider the cover-glass examination as being conclusive. The results of the cover-glass examination must be controlled by cultures in which the suspected coccus is isolated and its identity proved by its cultural peculiarities. From the standpoint

of the pathologist, the chief interest today attached to the gonococcus is the role it plays in inflammatory processes other than urethritis. It does not suffice to prove that a given case of arthritis is due to infection with the gonococcus by showing that cocci decolorized by Gram's method are contained inside the pus-cells of the exudate, but in addition it must be shown that these cocci will grow only on special culture media and it must be rigidly determined that they will not grow on ordinary culture media. Furthermore it must be shown that these colonies on special culture media have certain appearances, and that the micrococci composing such colonies are decolorized by Gram's method and have a decided tendency to group in fours. The culture must not be more than 48 hours old, because some cocci that voluntarily stain by Gram's method have been observed to be decolorized when the cultures are older. The cover-glass propagation of colonies should not be made too thick, and the judgment as to whether the coccus decolorizes or not after treatment with Gram's method should be made only from portions of the field in which the cocci are well separated from one another. [J.M.S.]

3.—Balch believes that it is very doubtful that an injection of any antiseptic substance would prevent an attack of gonorrhea after a suspicious connection. Theoretically, such an injection should be an extra safeguard, because the gonococci would not have penetrated the cells and could easily be reached by an antiseptic. It is best to treat an acute case of gonorrhea twice a day during the first week or 10 days of its course and after that the patient should use an injection himself 2 or 3 times a day for 2 or 3 weeks longer. As injections for abortive treatment Balch only believes in silver nitrate, permanganate of potassium, and protargol. He employs a solution of 1 grain to the ounce of silver nitrate. If there is no evidence of very active inflammation he uses 2 grains to the ounce. It is unwise to use stronger solutions than this. When permanganate of potassium is used from the beginning instead of silver nitrate, it is best to irrigate with a large amount of a weak solution, such as 1 to 4,000, rather than with a little of a stronger one. Where it is impossible to see a patient as often as these two methods require protargol is a safe injection for him to use himself. A $\frac{1}{2}$ solution is as strong as it is best to begin with, and if there is any great amount of scalding this should be diluted. With all 3 of these methods it is often necessary to give a mild astringent injection at the end to get rid of the final gluing together of the lips of the meatus in the morning. If the patient presents himself only after the disease has been fully developed for several days, and there is a thick, yellow discharge with scalding, painful erection, etc., there is no use in trying to abort the trouble. If an injection is used at all it should be very mild. It is usually safest to give no local treatment for a time, but to rely on medicine. The citrate and acetate of potassium are useful, chiefly because they make a patient thirsty. The same result can be accomplished by making him drink water as a medicine. It does not upset his digestion at least 2 quarts a day should be drunk. Compound salol capsules are good and should be taken after meals and before going to bed. Urotropin has not done so well as it was at first hoped it would. It must always be borne in mind that while an injection can cure a discharge it can also keep up one. In obstinate cases it is occasionally surprising to see how quickly the discharge will cease when all treatment is stopped. [J.M.S.]

4.—Clinically acute gonorrhea in the female is much less frequent than in the male. The disease is not, as in the male, always preceded by a period of acute invasion, the symptoms of which necessarily attract the attention of the patient and the physician, and for this reason gonorrhea in women is often overlooked. It is sometimes better to examine near the menstrual period, because at that time the congestion of the pelvic organs increases the discharges, and it is probable that more gonococci are thrown off. The experiments of Wertheim explain the fact that a subject of chronic gonorrhea may infect his hitherto uninfected wife, and become again infected from her; that is, the gonococcus, by passing through the new culture of the wife, again becomes virulent for the husband. If we are called upon to pronounce when a woman is entirely free from the danger of transmitting gonorrhea, it is at once apparent that we have to face a more complicated problem than we have in

the case of gonorrhea in the male, because of the many possible lurking places for the gonococcus in the sexual organs of the female. As a practical matter we may say that a woman is cured of gonorrhea when there are no signs of chronic inflammation about the pelvic organs, and when two or more negative cultures have been taken from the urethra and the cervical canal. As a germicide, protargol, in solutions of from 1% to 5% seems to be displacing silver nitrate as the standard remedy, and has given better results than the many other salts of silver. [J.M.S.]

5.—The points at which a subsiding inflammation of the urethra most commonly lingers are the penoscrotal angle and that portion of the pendulous urethra just anterior to it, the bulbomembranous junction, the prostatic urethra, and the fossa navicularis. In the treatment of chronic gonorrhea, the objects to be aimed at are the removal of fibrous deposits, the restoration of the thickened and rigid mucous membrane approximately to its original soft and elastic condition, and the cleaning out of diseased follicles and glands. The first principle of this treatment is dilation. After dilation, the local application of various remedies is effected by means of injections or irrigations, and later the urethra is inspected through the endoscope and local applications made under control of the eye to such points as require them. [J.M.S.]

6.—**Seminal vesiculitis** may be either acute or chronic. Direct gonorrheal infection is extremely rare, but when it does occur it is very acute and of an extreme type. The contents of the vesicle become purulent, the vesicle wall and the perivesicular tissues are involved, and occasionally the peritoneum, which lies close to the summit of the vesicle, is also implicated. There are a few cases reported in which a general peritonitis has resulted from such peritoneal involvement. Aside from the gonococcus, in certain cases presenting the signs of an acute seminal vesiculitis, the only organism found present has been the colon bacillus. It is probable that infection may take place, therefore, not only by continuity along the surface of the urethra and through the seminal duct, but also by direct invasion from contiguous tissues, such as the rectum. The symptoms of acute seminal vesiculitis are almost wholly inflammatory in character. While the acute inflammatory process is at its height the urine may be nearly clear, but it becomes purulent with the decrease of the symptoms and the escape of pus from the vesicular cavity. The involvement of the perivesicular tissues is determined by rectal palpation of the vesicles. At the outset measures directed toward checking the inflammatory process should be taken. If the pus is present it should be evacuated by incision and drainage either through the rectum or through the perineum. Chronic vesiculitis is due either to indirect gonorrheal infection or to tuberculous infection. Symptoms of chronic seminal vesiculitis of gonorrheal origin are functional or neurotic in character. Complaint is made of perverted sexual desire, irregular seminal emissions, and neurotic sensations. The treatment by massage of the vesicles should be instituted before resorting to extirpation, which, in turn, should be reserved for those extreme cases that are associated with serious or severe subjective symptoms. There are 3 routes by which the seminal vesicle may be reached, the inguinal, the perineal, or the sacral. Details of the different operations are given. [J.M.S.]

7.—The processes involving the prostate, that accompany, complicate, or are dependent upon a preexisting or coexisting gonorrheal urethritis, may be either acute or chronic, and last from 3 days to several years. In extent these processes may be limited to the prostatic follicles, they may involve the entire organ, or they may penetrate the capsule and extend to the surrounding tissues. In intensity they may be of any degree from a simple congestion with vague symptoms, to rigors, fever, prostration, and death. **Infection of the prostate** may come by direct extension from the urethra, by the blood or the urine, or by continuity of tissue. In gonorrhea the infection always comes from the urethra and from a preexisting posterior urethritis. It is evident, therefore, that it may be due either to the gonococcus alone, or to a mixed infection. Clinically, a posterior urethritis always precedes a prostatitis, even though the latter be due to manipulations with unclean instruments. Anything that irritates or tends to increase the congestion accompanying a posterior urethritis may act as an exciting cause of a

prostatitis. Among many agents may be mentioned alcohol, coitus, prolonged sexual excitement, exposure to cold, forcible and injudicious injections, horseback riding, bicycling, and such violent exercise as running and jumping. The jolting coincident to a railroad journey may be a determining factor. Prostatitis usually appears at the end of the second or during the third week of urethritis. The acute cases may be of the type of simple congestion; of inflammation limited to the follicles and perifollicular tissues; of a process involving both follicles and parenchyma and progressing to pus formation of greater or less degree, and, finally, of a process involving almost the entire gland and extending to the periprostatic tissues. The chronic type is almost always follicular, although it occasionally is characterized by one or more small abscesses that develop without the majority of the typical symptoms. The duration of the acute congestive and follicular types is from 3 days to 3 weeks; of the parenchymatous and purulent types from 1 to 3 months, and of the chronic type for months or years. Retention of urine is present in a large proportion of cases; it may be relieved by repeated catheterization; by inserting a small catheter and leaving it in place, or by aspirating over the pubes. Unless we desire to utilize the catheter to facilitate discharge of the abscess through the urethra, aspiration is the method of choice. If the abscess points into the rectum the fluctuating point may be incised with a bistoury. [J.M.S.]

8.—It has been estimated that from $\frac{1}{3}$ to $\frac{1}{2}$ the existing cases of blindness have been caused by gonorrheal inflammations of the eyes, generally as a result of infection of the cornea and the ulceration and sloughing that often destroy more or less of that tissue. The disease generally occurs in infants, beginning from 1 to 5 days after birth, or in young adults, and in almost all cases is caused by carrying to the surface of the conjunctiva some of the diplococci of Neisser. Other pyogenic organisms may give rise to a **purulent conjunctivitis** similar to the true gonorrheal form, so that it is not possible in any given case to say that the trouble must be due to gonorrheal infection without making a bacteriologic examination. The inflammation of the conjunctiva will disappear in time without any serious results to vision, but the principal attention must be constantly directed to the condition of the cornea, to prevent, if possible, the infection of its tissue with the purulent matter. For this purpose the first and most important treatment is the careful removal of the purulent discharge. This should be done every 15 minutes or $\frac{1}{2}$ hour, if necessary, night and day for the few days the disease is at its height, and at longer intervals as the discharge decreases. In the early stages of the disease, applications of cold may be made, but should not be continued if corneal complications arise. Williams believes that silver nitrate solutions should not be used in the early stages, but in the later stages of the disease, after the intense swelling of the eyelids has begun to subside and the discharge is more purulent, a 2% solution may be applied to the conjunctival surface and then neutralized with salt-solution. Nothing, however, should take the place of the constant cleansing. Solutions of protargol appear to be less reliable than silver nitrate. The edges of the eyelids and the surrounding skin should be protected with vaseline. In patients who are in poor physical condition, the application of heat will often prove better than cold. If the cornea becomes hazy and a small ulcer forms, continue the irrigation, use 1% atropin 3 times a day, and hot applications rather than cold. In some cases of marginal ulceration solution of eserine, $\frac{1}{2}$ grain to the ounce, may be used every 4 hours, but it must be used with care. The number of cases of ophthalmia neonatorum have been greatly reduced by the prophylactic treatment of Credé. In adults, if the disease has only affected one eye, the other eye should be at once protected by covering it with a small pad of absorbent cotton and gauze. [J.M.S.]

9.—**When is gonorrhea cured or ended?** We must admit at the beginning that the question cannot be answered. The medical world is united in realizing that gonorrhea is not the simple disease it was once considered, but is one that often spreads to places in which its local treatment is impossible; which very often becomes chronic, and sometimes defeats the efforts of the most expert for its eradication; which in very many instances retains its contagious capabilities long after its very existence is supposedly ended. Physicians can use every effort to prevent the exposure of innocent women to this infection, and can teach the rest of

the world, both medical and nonmedical, the necessity for being similarly careful. According to Thorndike, the methods of examination at present at our command are fairly adequate to determine in any individual case whether there are still contagious possibilities in that case. The methods of treatment at present at our command are fairly adequate for the treatment of those cases in which remnants of disease are found. All such remnants of disease should be treated, whether they contain gonococci or not. There are a few cases in which the remnant of discharge persists, but in which no cause for its persistence can be found, in spite of many most careful efforts. Some of these cases must probably be allowed to marry with traces of discharge still discoverable; but none such should marry until every possible effort has been made to demonstrate the noncontagious character of the pus and until the possibility of future trouble has been explained. [J.M.S.]

1.—Dawbarn urges the advisability of saving all blood possible in every operation, and then discusses the various means of doing this. In operations upon the extremities the milking of the part while it is elevated, and the application of an Esmarch tube is recommended. In operations upon the leg, the middle of the thigh is the best point for the application of the constricting tube, thus avoiding the external peritoneal nerve; in operations on the forearm, the tube should be applied in the lower or upper third of the arm, thus avoiding pressure of the musculospiral nerve. In operations upon the scalp the blood supply can be controlled by the application of a constricting elastic band around the head. Bloodless operations upon the breast can be done by passing 2 long mattress needles underneath the gland, and below them a constricting rubber band. In operations upon the bladder, perineum, and genitals, in both males and females, the Trendelenburg posture is of great advantage. Dawbarn then discusses the cording of the extremities to prevent bleeding within the abdomen, thorax, and skull. By keeping the blood in the extremities, clotting in the visceral cavities is hastened. He thinks this a good treatment in cases of apoplexy, particularly if instituted early. Only 3 limbs should be corded at one time, and the cording should be carried out in regular rotation. The application of the Esmarch bandage and tube over injuries about the joints where there is a great deal of swelling for the purpose of thoroughly examining the bones, Dawbarn has often found useful. In performing the operation of tonsillectomy the author's method of constricting the base of the tonsil with a purse-string suture is recommended. The application of first suprarenal extract and then cocaine to the mucous membrane of the bladder, rectum, and vagina is found useful in controlling bleeding in operation on these organs. [J.H.G.]

2.—Murphy first discusses briefly the history of spinal analgesia as first proposed by Corning and first practised by Bier. Of 631 cases collected by Murphy of subarachnoid cocainization there was perfect analgesia in 45%, partial in

2.21%, and in 3.32% it was a failure. But one death has been reported and that in Tuffier's clinic. It is a question whether this death was not due to cardiac lesions, found postmortem, and not to the use of the cocain. Physiological effect: The effect is produced by direct application of cocain to the posterior roots and ganglia and not to the cord itself. The sense of contact is not affected, the reflexes are slightly diminished, some incoordination is usually present, intestinal peristalsis and uterine contractions are usually stimulated, while the sphincteric action of the bladder, vagina and rectum are often completely abolished. Dosage is next discussed, and the sterilization of the solution used. Murphy has used with satisfaction the glass ampullae containing the solution which had been prepared by certain well-known and trustworthy manufacturers. The point of introduction is a space between the fourth and fifth lumbar vertebrae, one-half inch from the median line, the patient occupying a sitting position. In some cases of spinal deformity it has been impossible to insert the needle at this point. Injections have been made between the sixth and seventh cerebral vertebra. Murphy thinks this, until further investigation has been made, an operation not free from danger. The fluid should never be injected except when the cerebrospinal fluid is flowing from the needle, and it should always be injected slowly, requiring from 40 to 60 seconds. Symptoms: First there is a sensation of heat passing over the entire body, then that of thirst, followed in a few minutes by nausea, which may last for 10 minutes. Preceding the vomiting there is increased rapidity of pulse, pallor, and respiration. These symptoms last for a few minutes usually, but are in some cases very marked and make stimulation necessary. Murphy thinks that hyoscin hydrobromate, $\frac{1}{100}$ of a grain, and nitroglycerin, $\frac{1}{100}$ of a grain, are the best stimulants under the circumstances. The analgesia usually appears in from 3 to 10 minutes, though sometimes it may be delayed from 20 to 30. It usually begins in the feet and gradually ascends, though in rare instances it may first appear as a band around the body and then descend. And in rarer instances still it has been known to ascend from the level of the injection and involve the upper extremities, the neck, and face. Amputation of the breast has been performed by this method. The duration of the analgesia may extend from 12 minutes to 5 hours. Muscular rigidity sometimes interferes with abdominal work. This method may be employed at all ages. Symptoms: Headache, lasting several hours to several days, is a usual post-operative symptom. Prolonged vomiting is unusual. Vertigo and some ataxia in gait may persist for some days. The temperature usually rises after the operation. On the day after the operation the patient is in a much better condition than when chloroform and ether have been used. Coma and delirium both have been observed in some cases. Mental exaltation from cocain is frequently observed. Failure to obtain analgesia after the employment of this method Murphy thinks is due to faulty technic or personal idiosyncrasy. [J.H.G.]

3.—The muscular, fibrous, and vascular portions of the eyeball render it particularly susceptible to **rheumatic affections**. According to the author some diseases of the eye due to chronic rheumatism are iritis, episcleritis, scleritis, ocular palsy, glaucoma, and vitreous opacity. The author reports a case of iritis, episcleritis, and scleritis, all of unquestionable rheumatic origin. He considers deep scleritis as the most serious, but also as a rare ocular disease due to rheumatism. [M.R.D.]

4.—Thayer gives a thorough review of the literature of the interesting subject of the **relationship between ovulation and menstruation**. He concludes from his investigations that menstruation is no integral part of ovulation, nor an absolute factor of conception, though these two conditions are usually concurrent and attendant. In accord with the general belief, he states that there may be ovulation without menstruation, and menstruation without ovulation, and conception without menstruation. [W.A.N.D.]

5.—Harrison, by reference to the literature, presents an interesting anatomic description of the source and extent of the distribution of the cerebrospinal and sympathetic nerves to the pelvic organ, and at the same time demonstrates the communication between them. He also shows that in the sympathetic paths vasomotor, secretory, and sensory fibers run, and from this intimate relationship it is easy to explain

the various morbid phenomena of **dysmenorrhea**. With reference to the causes of dysmenorrhea it is the common practice to refer the phenomena to diseases of the uterus, the tubes, the ovaries, and the peritoneal covering of these organs, as well as to the pelvic connective tissue. The etiological factors are generally to be found in inflammatory processes. He does not believe that dysmenorrhea in its full type, if allowed to persist unchecked, will undoubtedly cause oophoritis and endometritis, as has been stated to be the case. He calls attention to the fact that there may be a peculiar form of dysmenorrhea of nasal origin, the sensitive points lying in the inferior turbinate bones and the tubercular septi, which undergo changes during menstruation. [W.A.N.D.]

6.—Massey urges the intelligent use of **electricity in the treatment of menorrhagia of pelvic origin**. He claims that expertness is readily gained by those equipped with sufficient gynecologic and electric training, and though the actual work will require some time and trouble, the result, he states, cannot be other than pleasing when it keeps the patient at home, and makes her a well woman. [W.A.N.D.]

7.—Marcy presents a study of **movable kidney**, as seen by the general practitioner. He states that the medical treatment of this condition should consist in the use of such measures as would improve the general health of the patient, together with the accumulation of surplus fat. The rest-treatment, with forced feeding and massage, is sometimes beneficial. As a tonic he prefers tincture of nux vomica in large doses, together with cold douching of the spine followed by brisk rubbing. The mechanical treatment consists in the use of elastic bandages, sometimes fitted with a special pad, called a **kidney-pad**; this device sometimes relieves the symptom but does not always keep the kidney in its proper place. The ideal treatment is surgical. [W.A.N.D.]

8.—Duffield, in an article entitled "Some Notes on the Climatology in Arizona," states that there is a great diversity of climates in Arizona, varying from subtropical to that of the high mountain elevations. The advantages of the climate are a dry atmosphere, a low percentage of humidity and a high percentage of sunshine. Arizona offers an elevation of 13,000 feet above sea level, and the State is well supplied with mineral and thermal springs. [F.J.K.]

9.—Mitchell in an article gives the **preventative treatment of migraine**. Meals should be taken at regular intervals and great care must be exercised in not overfeeding the patient. Especial precautions should be used in excluding rich and highly seasoned food. The patient should not be allowed red meats, and stimulants must be excluded. Fish, bacon, brains, sweetbreads and eggs may form part of the diet. Outdoor exercise and frequent bathing are recommended. The important indications in medicinal treatment are to regulate the bowels, to keep the liver active, and promote intestinal antiseptics. The drugs which are indicated are the various salicylates, and mercurials. He gives a formula recommended by Dr. Rachford, which is as follows: sulphate of soda 120 grains, phosphate of soda 30 grains, salicylate of soda 19 grains, tincture of nux vomica 3 drops, distilled water to make 4 ounces. This dose is to be taken before breakfast. Water should be partaken of in large amounts. [F.J.K.]

10.—Greenly recommends the **injection of salt-solution** into the lower bowel in the treatment of **threatened collapse from hemorrhage**. He uses an ordinary fountain-syringe or a common hand-syringe for the purpose of introducing the fluid into the rectum. The solution should be heated to a temperature of from 110° F. to 115° F. A gallon of water should contain 1 ounce of sodium chlorid. He believes that the rectal injections of salt-solution are preferable to hypodermoclysis or intravenous injection. He has treated collapse following hemorrhage with good results. [F.J.K.]

11.—In speaking of the **physiologic resuscitation of the stillborn** Lichty remarks, that there is an anatomic and physiologic area or center in the medulla oblongata which is recognized as presiding over respiration is no longer a subject of doubt or discussion. The group of dynamics stored in the centers coordinating respiration is very complex and of wide distribution, as evidenced in impending asphyxia, dyspnea, or aroused respiration, when nearly all the muscles of the trunk are called into requisition, reinforced by the rigid extremities which fix the trunk as auxil-

iaries. Resuscitation in most cases of asphyxia is accomplished by prompt depression of the upper zone of the body, to favor gravitation of the blood, to the dependent cerebellar region and medullary center. Next in importance to this is the supplying of artificial heat externally; and the supplementary pressure of the capillaries by the subcutaneous subperitoneal, or rectal flushings with the normal salt-solution. This is the method as used in adults, and Lichty believes that it would be just as efficacious in the case of a newborn child. [W.A.N.D.]

12.—Barbat records a case of **right-sided ectopic pregnancy**. The case is of interest on account of the meager symptoms, and the fact that the ovum, which was extruded from the left ovary, was fertilized in the left tube. [W.A.N.D.]

Berliner klinische Wochenschrift.

December 24, 1900. [37. Jahrg., No. 52.]

1. Contributions to the Normal and Pathological Histology of the Human Hypophysis Cerebri. C. BENDA.
2. A Grave Spinal Symptom-complex Caused by a Serpentine Aneurysmal Change in the Spinal Bloodvessels. F. BRASCH.
3. Extirpation of the Hypophysis Cerebri. F. F. FRIEDMANN and O. MAAS.
4. Amyloid Degeneration, with Special Regard to the Kidney. M. LITTEN.

1.—In preparing sections of the human **hypophysis** for microscopic examination, Benda has found that the best staining methods are the blood-staining methods of L. Michaelis, Weigert's method for staining fibers, the author's iron-alizarin-toluidin-blue stain, and finally also Weigert's or Pal's methods for staining medullary sheaths. In four cases of akromegaly the author found the hypophysis enlarged, and in two cases tumors were found. The author will not admit without qualification that enlargement of the gland is responsible for the increase in size of the osseous system. [M.R.D.]

2.—Will be abstracted when concluded.

3.—The authors have devised an operation for **extirpation of the hypophysis**, by means of which animals may be kept alive for months after the operation. They believe that the hypophysis is not necessary for the maintenance of life. In no case have the authors upon postmortem examination found any change in an organ which could have been attributed to the absence of the hypophysis. The technic of the operation is described in detail. [M.R.D.]

4.—Frequently a combination of large white kidney and **amyloid** change in its vessels is seen. Neither macroscopic nor microscopic examination will reveal the condition, but only the chemical test. This variety of kidney is much larger and heavier than normal, averaging from 250 to 400 grains. The increase in size affects equally all diameters. The delicate thinned capsule is easily stripped off without adhering to the parenchyma. The surface of this kidney is strikingly anemic with an occasional yellowish tinge. The consistency of the organ is firm. The cut surface of the kidney has the same waxy luster as the external surface. In the amyloid contracted kidney the customary changes associated with amyloid degeneration are found. Thionin is stated to be the only stain which colors amyloid material sky blue, while other substances will be colored a reddish violet. In the majority of cases of amyloid kidney the urine is of fair quantity, pale yellow, clear and of a low specific gravity; upon long standing hardly any sediment can be seen. The author believes that an increase in the quantity of urine is not as frequent as has been supposed. Furthermore there is no other renal affection in which the urine varies so markedly. The urine does not show a systematic array of conditions, characteristic for amyloid degeneration of the kidney. It has been stated that waxy casts are seen; but there is no reason why albumin casts may not be the subject of amyloid degeneration. Litten believes that albumin in the urine is absolutely necessary for the diagnosis of amyloid degeneration of the kidney. The albuminuria may be constant or recurrent. [M.R.D.]

1. The Treatment of Chronic and Infectious Ulcers by Hot Air. CARL ULLMANN.
2. The Ability of Bacteria to Pass Through the Intestinal Wall. HUGO MARCUS.
3. A Case of Pemphigoid Measles. J. ZUHR.

1.—Ullmann reviews the literature, telling how many chemical substances have been used as counterirritants upon infected wounds, ulcers, etc., to produce local hyperemia. Phototherapy, Röntgen-rays, etc., have the same effect. But the simplest and oldest of all is heat. Hitherto this has been applied as the cautery, as conducted, or as radiated heat. He quotes a case of serpiginous ulceration of the groin, in a man 28 years old, described by Haslund, treated by cautery first without improvement, and then placed in a permanent hot-water bath for 19 days. This treatment completely healed the wound. He has used hot air in about 150 venereal and nonvenereal ulcers. The apparatus used is then described. It covers the male genitalia, wrapped in wadding, after the adjustment of which the temperature of the enclosed dry air can be raised to 150° C., and is kept there from half to over an hour. A local hyperemia results, with some edema, but no constitutional symptoms therefrom. The air must be dry, so that no burns occur. He reports a case of venereal ulceration, operated, and then treated thus, with recovery in 8 days. The details of 10 more cases of indurated ulcers follow, all cured by this treatment. [M.O.]

2.—Marcus replies to the criticisms made by Posner upon the method of performing his experiments to test the ability of bacteria to pass through the intestinal wall. He reports 6 new experiments upon animals (with 2 control experiments), in all of which infection of the urine followed, and in one instance, general infection. From these it is striking to note that when the urine was infected the blood was not. The one positive result of all his experience is the fact that with decided coprostasis, the bacteria in the intestines never reach the blood. [M.O.]

3.—Zuhr reports a case, a boy 8 years old, who developed typical confluent measles with huge blisters scattered throughout the eruption. There was albumin in the urine. The diazo-reaction was negative. All the other symptoms of measles were present. The fever remained high, and death occurred in 10 days. Zuhr considers it a rare case of pemphigoid measles. [M.O.]

Deutsche medicinische Wochenschrift.

December 27, 1900. [26. Jahrg., No. 53.]

1. Concerning Experimental Descending Tetanus. L. ZUPNIK.
2. The Reaction of the Prostatic Secretion in Chronic Prostatitis and its Influence upon the Viability of Spermatozoa. H. LOHNSTEIN.
3. Sunstroke. M. HERFORD.
4. Therapy of Croupous Pneumonia. A. TAGESSON-MÖLLER.
5. Colpocleisis with Artificial Rectovaginal Fistula in a Case of Incurable Vaginointestinal Fistula Due to Recurring Carcinoma. H. SAFT.
6. Concerning the Presence of Sebaceous Glands in the Mucosa of the Cheek. LUBLINSKI.

1.—Zupnik has been able in a series of animals of different species to produce a typical descending tetanus which was in its symptoms practically the same as that which occurs in man. This was done by inoculating the animals about the feet or ankles. If the animals were inoculated about the peritoneum or groin, an ascending tetanus occurred. This seems to explain the usual occurrence of an ascending tetanus in animals—the character of the disease depends upon the point of inoculation. The minimal fatal dose of the toxin was also variable according to the point of inoculation. More toxin was required when the animals were injected about the feet. [D.L.E.]

3.—Herford reports several interesting complications of heat stroke. Those chiefly spoken of are: disturbance of speech, bleeding from the intestines, and acute icterus. A case in which there was severe intestinal hemorrhage died,

and the postmortem showed marked hyperemia of the gastrointestinal tract and other organs, and the liver looked like the liver of acute yellow atrophy. There were scattered small hemorrhages in the brain. The importance of this find upon autopsy is indicated by the course of 2 cases of speech disturbance. The patients exhibited marked ataxia after the heat stroke, with very decided disturbance of speech. In one case these symptoms improved fairly rapidly, and had almost completely disappeared at the time of the report. The other patient had shown comparatively little improvement, and seemed unlikely ever to recover entire health. The cases resemble the instances of acute ataxia reported by Leyden, and the combination of ataxia and speech disturbance and other less striking symptoms remind one of multiple sclerosis. The probable cause of these symptoms in Herford's belief was scattered small hemorrhages in the brain. [D.L.E.]

4.—The treatment of pneumonia recommended is manipulation of the chest by various forms of massage, friction, vibratory exercises, etc., by means of which it is claimed pain can be well controlled, the breathing can be improved, the strength of the heart action can be increased, and the course of the lung changes themselves can actually be favorably influenced. [D.L.E.]

6.—Lublinski describes at some length one case, and more indefinitely a series of cases in which he has observed sebaceous glands in the mucous membrane of the cheeks. The one patient whose case was described at length was a physician. The inner surfaces of the cheeks were covered with numerous small yellowish papules which produced no subjective sensations. There was no history to explain their occurrence. Other patients in which they were observed had usually a history of excess in the use of alcohol or tobacco, dyspepsia, the use of mercury, or other similar causes. They were not infrequently seen in diabetes and gout. They usually appeared in the interdental spaces, and were comparatively rare on the lips. They commonly caused no symptoms, and were accidentally discovered. Microscopic examination, which was undertaken in a number of cases, showed that they were undoubtedly sebaceous glands. [D.L.E.]

5. Pathogenesis of Gonorrheal Epididymitis. D. BASKAL.
6. Etiology of Dysentery. DRYCKE.

2.—Wassermann reports in brief an experiment which shows, in his belief, that the natural resistance to disease is due chiefly to the presence in the organism of complements (alexines); that is, there are present in the normal blood ferment-like substances which have the power to destroy bacteria, and they are the chief shield of the organism from infection. His experiment consisted in injecting normal guineapigs with an agar culture of typhoid bacilli mixed with normal rabbit-serum. These animals lived. If instead of the normal rabbit-serum the serum was taken from rabbits which had been injected with normal guineapig-serum, the infected guineapigs died. The serum of the latter series of rabbits contained anticomplements (antialexines). In animals infected in this way it was observed that the peritoneal fluid about an hour after infection showed large numbers of motile typhoid bacilli, an evidence that the organism in these animals had not controlled the infection. On the next day the animal was usually found dead. [D.L.E.]

3.—Blumenthal and Neuberg briefly discuss the question as to the origin of acetone, and note that the general tendency recently has been to consider that acetone and its congeners are produced only by fats, and it has recently even been stated that protein does not produce acetone or its congeners. They note that some authors consider that they have produced acetone from casein, and then report their own experiments. It has been shown by a number of authors that iron salts are very important in oxidative processes in the body. They, therefore, took gelatin solutions,

added peroxid of hydrogen, and then added a soluble iron salt (ferrous sulfate). The vessel containing this mixture was put in an oven and frequently shaken. After 3 to 5 days they found that the peroxid of hydrogen had disappeared. They then distilled the fluid, and in testing the distillate found an aldehyde present, and also, with the hydroxylamin test, found that there was a ketone present. They then carried out the P-nitrophenylhydrazin test, and got a pronounced reaction. They, therefore, consider that they undoubtedly produced acetone and aldehyde from gelatin (which is a protein), and think they thus demonstrate the possibility of its occurrence in this way in the body. They also consider that one must admit that the iron salts may have an important role in oxidative processes in the body. [D.L.E.]

4.—The authors give a general discussion of the methods of producing the serum, and its value in treating animals, both as a prophylactic and in the management of the actual disease. The serum is now produced in a way which allows of an exact measurement of its value, and is obtainable on order. [D.L.E.]

6.—Deycke, in referring to Kruse's recent article in this journal, states that while working in Constantinople he found that it was possible in most cases of dysentery to obtain a bacillus in much larger numbers than any other organism, and this bacillus seemed to belong to the colon group and resembled the bacillus of typhoid fever. It almost constantly produced typical severe dysentery in cats, and this was usually fatal. The postmortem changes found were, losses of mucosa, petechia, erosions, sometimes ulcerations and general swelling of the mucous membrane of the colon. The small intestine was uninvolved. The histological changes were entirely analogous to those seen in man. [D.L.E.]

2.—Bendix briefly reports that he has obtained a characteristic orcin test and a typical osazon of pentoses by proper treatment of the bodies of typhoid bacilli, as well as a series of other bacteria. He therefore feels convinced that pentoses are present in these organisms. He has also apparently shown that the nucleoprotein of the bacteria contains the pentoses, and the nucleoprotein is probably the chief or sole carrier of the pentose radicle. It has been shown that higher organisms contain pentoses chiefly in union with nucleoproteins. This work is therefore further testimony of the similarity of the higher and lower organisms, and it is shown that bacteria are able to take comparatively simple bodies, and, by synthesis, produce the characteristic nucleus of complicated composition from them. [D.L.E.]

4.—Becher recommends that the lower border of the stomach be determined by introducing a soft stomach-tube, and then pouring through this a suspension of bismuth, and at once examining the patient with the fluoroscope and marking the shadows seen with Levy-Dorn's special pencil. He states that it is unnecessary to fill the tube after the complicated methods recommended. By the simple method he recommends one sees the tube readily, and the shadow can easily be seen where the bismuth suspension has reached the lower border of the stomach. He considers this an exact and rapid method. [D.L.E.]

5.—The case is reported of a child 7 months old which was brought into the out-patient clinic in moribund condition, and died within two hours. The postmortem examination showed a very large thymus gland, the weight being about 40 grams and the measurements 8 cm. by 6 cm. by 4 cm. The heart was hypertrophied and dilated, and the aorta was dilated up to the point where the thymus gland compressed it,

and narrowed its lumen. At this point there had been severe compression of the aorta (at about the middle of the arch), and Kohn considers that it had undoubtedly produced the cardiac dilation and hypertrophy, and had caused death in this way. There has been much discussion as to the cause of death in disease of the thymus and it has been denied that pressure of the thymus could have this result alone. In this case it seemed to be unquestionable that a fatal result had ensued in this way. [D.L.E.]

6.—Wolowski describes at length a method for the quantitative estimation of indican, which he states can be carried out within a half hour, and which he considers gives results which are satisfactory for clinical purposes. The details are too elaborate to allow of a complete description. It depends upon precipitating out the albumins and then the pigment (with lead), and then adding to known quantities of urine varying numbers of drops of a solution of hypochlorite of calcium and some hydrochloric acid, then adding chloroform and ultimately learning the amount of hypochlorite that it takes to destroy entirely the color reaction. He makes the rather remarkable statement that in many diseases indicanuria is the sole cause of the disease. Possibly it is meant that it is the index to the severity of the affection and to its origin. He found in many skin conditions, particularly in some cases of asthma, in many cases of vertigo, in a case of epilepsy, in many gastric and intestinal affections, and in numerous nervous diseases, particularly the neuroses, that the indican was largely increased, and as the disease improved the indican disappeared more or less completely from the urine. The treatment which he recommends is biniodide of mercury with intestinal lavage. [D.L.E.]

Journal des Praticiens.

1. Disturbance in the Innervation and Circulation of the Heart in Infectious Diseases. JOSEPH PAWINSKI.
2. A Case of Gonorrheal Myelitis. M. LABBÉ.

1.—After a historical review of the work done by the men who discovered the relation of myocarditis and other changes in the innervation and circulation of the heart to the infectious diseases, Pawinski reports 3 cases in full. The first, a man of 45, hereditarily neuropathic, had influenza pneumonia after mental overwork; the second, a man of 50 years, after a brother had died of aneurysm, had follicular tonsillitis; and the third, a woman aged 50 years, who smoked cigarettes continually, had influenza after having had an operation under chloroform. Each attack was accompanied by severe nervous and cardiac symptoms. After discussing the possibility of their being cases of mixed infection, Pawinski inclines toward believing that they were not. He thinks that the nervous and vasomotor mechanism of the heart did not functionate well in these cases even before the infection; thus, after the arrival of the influenza or pneumonia bacilli, severe cardiac attacks are at once understood. As treatment he advises rest in bed, milk diet, and the usual heart stimulants, caffeine, camphor, strychnin, etc. [M.O.]

2.—Labbé reports the case of a man, aged 35, who entered the hospital with gonorrheal arthritis existing for a month in both legs. He had taken salicylates without improvement. Both knees were affected, both legs were paralyzed, and he complained of painful micturition. These symptoms grew better gradually, yet the "blenorragic foot of Jacquet" remained associated with a spasmodic paraplegia, marked when he attempted to walk. The muscles of both legs atrophied, and Babinski's reflex was found. Syphilis, the infectious fevers, and hysteria were all excluded. But for 17 years gleet had existed off and on, with gonorrheal arthritis. Labbé considers this a case of gonorrheal myelitis, with favorable prognosis. He advises sulphur baths, massage, and electricity. [M.O.]

The Government of India has sanctioned the establishment of a ward in the Station Hospital, Calcutta, for the accommodation of British officers returning to India from China, and also the enlistment of 2 nurses to attend them.

PERFORATING ULCER OF THE STOMACH; OPERATION; RECOVERY.*

By JOHN H. MUSSER, M.D.,

of Philadelphia,

Professor of Clinical Medicine, University of Pennsylvania,

AND

HENRY R. WHARTON, M.D.,

of Philadelphia,

Clinical Professor of Surgery, Woman's Medical College; Surgeon to the Presbyterian and Children's Hospitals.

G. C., aged 40, single, farmer, resident of Maryland. He used tobacco moderately, but no alcohol. He was regular in his meals, and his dietary was not an unusual one. He had had much care and anxiety.

Had dyspepsia for many years previous to present attack, chiefly of acid form. For 3 months prior to the date of the symptoms for which he required operation, he suffered from pain in the epigastrium, and occasional attacks of vomiting. He never vomited blood. The pain was often relieved by food, so that it was his custom to carry crackers and eat then when the gnawing became more pronounced.

It may be said, for many years the patient has been spare of build and rather gaunt, although quite strong. The pain became so severe and constant that he decided to come to Philadelphia to secure relief. On the morning of December 18, 1900, he arose early, partook of a light breakfast, drove to Annapolis, a distance of 15 miles. He arrived in Philadelphia at the office of Dr. D. Murray Cheston about 4.15 p.m. On examination Dr. Cheston found a tumor about the size of the fist to the right of the median line, just below the margin of the ribs. Further examination was postponed until the evening, when it was arranged the writer should see him in consultation.

At 5 p.m. the patient repaired to a restaurant to take his first food since early morning. At this hour he took a glass of soda water. He was at once seized with violent pain in the epigastrium and fell on the floor in a faint. He vomited and symptoms of collapse rapidly followed. He was removed to Dr. Cheston's office where Dr. Morris saw him suffering from severe general pain and collapse. Dr. Cheston saw him at 6.15 p.m.

The previously described tumor had disappeared. The pulse was 120. Temperature 97°. The abdomen was hard. The pain was general. The writer saw him at 8 p.m. having the good fortune to have the conjoint advice of Drs. Murray and Radcliffe Cheston. The condition was as indicated above. The writer was impressed with the extreme board-like rigidity of the flat abdomen. It was impossible to make any impression. The epigastrium was tympanitic. The pain was extreme and complained of in many situations. The patient complained of intense heartburn indicating some hyperacidity. There was no vomiting; some retching occurred, when esophageal and faucial burning was extreme.

The diagnosis of perforation of a gastric ulcer was made because of first,—the history of the case; second, the presence of a painful and tender tumor which disappeared suddenly; third, the onset of acute pain and collapse; fourth, the hyperacidity; fifth, the absence of signs of affection of the gallbladder or the appendix, or of pancreatic disease. Pancreatic hemorrhage and acute pancreatitis were considered possible, though not probable, because of the signs of tumor antecedent to the perforation, and because of the absence of the more prominent symptoms of pancreatic hemorrhage,—tumor and tympany.

It was our belief that general peritonitis was advancing rapidly, in spite of the subnormal temperature, because of the general pain, the increased pulse-rate and the rigidity of the muscles.

It remains to explain the presence and disappearance of the tumor. Without doubt perforation had occurred slowly

and a localized peritonitis had set in. The sudden pain and shock were due to the giving away of adhesions and the outpouring of the stomach-contents into the peritoneal cavity. With this accident the tumor disappeared.

It was fortunate for the good fellow, no doubt, that he had a long fast preceding perforation; that the opportunity for immediate operation could be afforded, and that 6½ hours after the perforation, his peritoneal cavity was being cleansed with hot salt-solution.

Dr. H. R. Wharton presented the following notes upon the case:

The previous history of this case has been given by Dr. J. H. Musser. I saw the patient on the evening of December 18, 1900, four hours after a sudden attack of pain in the epigastric region, which caused him to faint. When I saw him he was suffering excruciating pain, which he referred to the abdomen. He was slightly nauseated and was making ineffectual attempts to vomit. The temperature was 97°, the pulse 120. The abdomen was not markedly distended, but the abdominal muscles were so rigid that it was impossible to palpate any of the abdominal organs. He could not locate any especial point of tenderness, but complained loudly of severe pain all over the abdomen.

After consultation with Dr. M. Cheston, Dr. R. Cheston, and Dr. J. H. Musser, we decided that he was probably suffering from a perforated gastric ulcer, and that an operation was advisable.

He was removed to the Presbyterian Hospital, and 6½ hours after his first attack of pain an anesthetic was administered and it was decided to open the abdomen in the epigastric region, as the symptoms pointed strongly to a perforated gastric ulcer.

When the patient was fully under the influence of the anesthetic it was noticed that the rigidity of the abdominal muscles was only slightly diminished. An incision 3 inches in length was made from the tip of the ensiform cartilage towards the umbilicus, and as soon as the peritoneal cavity was opened it was found that a quantity of thin opaque purplish fluid escaped. The incision was slightly enlarged, and the surface of the stomach was exposed; this organ was grasped and partly removed from the abdomen and carefully examined for the presence of a perforated ulcer; the greater curvature, the lesser curvature, and the anterior and posterior surfaces were carefully examined and no ulcer was discovered. The stomach was replaced and the gallbladder next examined, thinking that this organ might have been ruptured, as masses of bile-stained mucus were noticed floating in the abdominal effusion. The gallbladder was found intact. The ascending colon was next sought for and drawn upwards, and the appendix inspected and found normal in appearance. The abdominal effusion was next removed by sponging, and it was then noticed that a small amount of fluid still continued to escape from the region of the pyloric end of the stomach. The stomach was next examined by drawing it outward, so that the posterior portion of the pyloric extremity was exposed to view, and there was disclosed a round opening, about ½ inch in diameter, from which fluid could be seen to escape. The perforation was situated on the posterior surface of the pyloric end of the stomach, about ½ inch from its junction with the duodenum.

Attempts were made to invert the edges of the opening by introducing silk sutures, but as the edges of the ulcer were undermined and very friable, the sutures cut through and without producing the desired result. There was also more or less induration of the tissues surrounding the ulcer, which prevented the inversion of the edges of the ulcer. I then decided to cover the ulcer by infolding the walls of the stomach by sutures introduced some distance from the perforation. This was accomplished by introducing six sutures of silk, which effectually closed the opening and prevented leakage, and after they were placed and securely tied, a few additional sutures were introduced at the ends of the infolded tissue. The abdominal cavity was next very thoroughly flushed with hot saline solution, about 8 gallons being employed. Two glass drainage tubes were next introduced, a long one extending downward toward the pelvis, and a shorter one passed upward in the region of the pylorus. The wound was then closed with silkworm-gut sutures, gauze drains were introduced to the bottom of the drainage tubes, and a copious

gauze dressing was applied over the wound and held in place by an abdominal bandage.

The patient was much shocked during the operation, but reacted gradually. The morning following the operation he was free from pain, his temperature was normal, and pulse was 80. The patient was given no nourishment by the mouth for three days, liquid nourishment and water being administered by the rectum. After this time milk in small quantities was given by the mouth. A free discharge of bloody serum occurred from the drainage tubes, which necessitated frequent changing of the dressings. The drainage tubes were removed on the fourth day, and small gauze drains were substituted for a few days. The patient suffered no further inconvenience and made an uneventful recovery, the sutures being removed from the abdominal wound on the thirteenth day. Four weeks after the operation the patient was discharged from the hospital and returned to his home.

Remarks.—Since Mikulicz, in 1880, first performed a formal operation for the exposure and closure of a perforated gastric ulcer, the procedure has been employed in many cases with most satisfactory results. A large number of cases in which operative treatment has been employed have been collected and analyzed by Mikulicz, Lindner, Barker, Weir, Lund, Mitchell, Tinker and Keen, and as the result of their studies much valuable information as to the most frequent site of the perforation, the prognosis, diagnosis, treatment and the details of the operation, have been added to surgical literature.

Perforation is comparatively infrequent in gastric ulcer, occurring according to various observers in from 6.5% to 18% of all cases. In Tinker's collection of 232 cases, only 22 cases of operation for perforation occurred in the United States. This accident is 5 times more frequent in women than in men. As regards the results of operations in Tinker's and Finney's combined collection of 268 cases, 139 recovered and 129 died, giving a mortality of 48%. In Tinker's collection of cases operated upon within 12 hours of the perforation, 75% recovered, and in a late collection of cases 83.78% of cases recovered. All observers agree that the best result is apt to follow in cases in which a short time only exists between the perforation and the operation.

The ulcer is more commonly situated upon the posterior wall of the stomach than upon the anterior wall, in the proportion, according to Pariser and Lindner, of 190 to 10, and is much more frequent near the pylorus than at the cardiac end of the stomach. Mayo Robinson has observed that chronic ulcers are usually situated near the pyloric extremity of the stomach.

The possibility of more than one perforation should not be lost sight of, for statistics show that in 20% of the cases this condition was present.

Death from perforated gastric ulcer results from peritonitis, caused by the bacteria which escape from the stomach into the peritoneal cavity at the time of perforation. Richardson considers that the size of the perforation, permitting a rapid escape of the stomach-contents, is an important factor in the development of a rapid form of peritonitis, producing, as he describes it, "a sudden overwhelming of the abdominal cavity rather than a spreading invasion."

The ideal method of closing the perforation is to excise the edges of the ulcer and bring them together by sutures. This, however, is only possible in exceptional cases, and in the great majority of cases infolding the walls of the stomach over the ulcer by sutures is the procedure which can be most rapidly and safely practised. Irrigation of the abdominal cavity and careful sponging have both been employed, but in my opinion

thorough irrigation is the safer procedure; drainage, either by glass tubes or gauze, is usually required, and pelvic drainage should be provided for, either by long tubes or by a counter-opening near the pelvis.

RECENT PROGRESS IN THE TREATMENT OF ACUTE LOBAR PNEUMONIA.*

By JAMES K. CROOK, M.D.,

of New York.

It may be doubted whether in the present state of our knowledge any definite routine of treatment suitable for all cases of pneumonia can be safely laid down. Weighing carefully the bulk of recent testimony, it would appear that many patients would do fully as well without any drug treatment whatever. According to Eichhorst,¹ for the past 15 years cases of uncomplicated pneumonia occurring in young and strong subjects have received in the clinic at Zürich no medication except a weak solution of phosphoric acid. Most of these patients have recovered, yet phosphoric acid cannot thereby be deemed a specific for pneumonia. The patients would have got well just the same without medicine. Even under the most unfavorable circumstances, as Osler points out, the disease may terminate abruptly and naturally without the administration of a dose of medicine. Young practitioners especially should bear in mind the fact that patients are more often damaged than helped by the promiscuous drugging which is still only too prevalent. All of the late writers whose opinions are most worthy of respect concur in the admonition to withhold drugs until the indications for them arise. Concerning the most desirable methods of meeting the indications, however, there is still more or less variance. But it will be seen that there are many therapeutic procedures regarding the value of which men of judgment and experience are practically agreed, so that the careful seeker after information may easily select a plan of treatment which, if it will not hasten the crisis or cut short the disease, will at least contribute to the patient's comfort and possibly tide him over dangerous emergencies.

On the Surroundings of the Patient.—There is no difference of opinion regarding the advisability of placing the patient in a cheerful, well-ventilated apartment with a temperature as nearly as possible between 65° and 70° F. If it is possible to do this, nothing is gained by covering the patient with the customary "pneumonia jacket" of cotton batting and oiled silk. A light flannel undershirt with the usual night-shirt or gown is much more conducive to the patient's comfort, and interferes less with the physician's examinations as well as with the application of local measures of relief. It is also agreed that the patient's food should be of a fluid character, wholesome and easily digested. Dr. Andrew H. Smith² calls attention to the fact that the adynamia is due to systemic poisoning and not to exhaustion, and cautions against the practice of overfeeding, which is liable to intensify the already labored respiration.

On the Use of Poultices, Ice, etc.—The time-honored custom of enveloping the affected side in a big flaxseed poultice does not meet with much encouragement in recent literature. Most writers ignore the subject altogether, and those who refer to it do so in terms by no

* Read before the Medical Society of the State of New York, Albany, January 29, 1901.

means enthusiastic. Broadbent³ states that poultices are distressing when assiduously applied, and thinks that a 3-hour application twice in 24 hours is sufficient. According to H. F. Williams continuous poulticing devitalizes.⁴ Blistering also appears to be losing favor. On the other hand, the use of cold applications, including ice-bags, has become a well-established therapeutic procedure and is endorsed by almost all recent writers. According to Thomas J. Mays,⁵ ice-bags applied to the head and chest relieve fever, lessen the tendency to convulsions in children, allay the irritation of the nervous system in adults, limit and check the extension of the pneumonic process by contracting the pulmonary capillaries, abate pain in the chest, support the function of the heart, and give rest and comfort generally. This method has the further advantage of being easy of application and of not being opposed by the patient's friends.

Few observers claim as much as does Mays for the ice-bag, but almost without exception the method is cordially recommended by recent writers. Sponge-baths also are generally advised. Hare⁶ recommends that after consolidation has taken place, hyperpyrexia be treated by cold sponging with friction and an ice-bag to the head and heart, but no internal antipyretics. It is doubtful if anything we can do for our patients is attended by less danger and is followed by more grateful results than are these entirely safe and simple procedures. (*Vide* articles by Raw,⁷ Walton,⁸ Williams,⁴ Dreschfeld,¹² and Rees.⁹) Baruch¹⁰ believes that most of the indications arising in pneumonia may be successfully met by properly applied hydrotherapeutics. According to Baruch, this method of treatment fortifies the nervous system, stimulates the heart, renders the patient comfortable by reducing high temperature and promoting sleep, and makes for the elimination of noxious products arising from the presence of the pneumococcus. The only discordant note is that of Sir Samuel Wilks,¹¹ who maintains that cold as well as hot applications are harmful. Cold applications are, of course, not to be used in afebrile cases occurring in old and feeble persons.

On Blood-letting.—Almost all recent writers deplore the general abandonment of the old-time method of blood-letting in pneumonia. There can be no doubt that our ideas regarding this procedure are undergoing a cautious revision. Sir William Broadbent voices the general sentiment as follows:³ "Venesection may be of great service when invasion of the lung is so rapid that the right ventricle cannot cope with the sudden resistance in the pulmonary circulation and is paralyzed by overdistention. Not less than 16 to 20 ounces should be removed. The same results are not obtained later when asthenia has become a prominent symptom, although there is still a dilatation of the right heart." Frederico Rubio¹⁸ believes the abandonment of blood-letting to have been a distinct loss. E. Michel¹⁴ highly extols the value of venesection as a standard method of treatment in the early stages of pneumonia, with the subcutaneous introduction at the same time of a quantity of Hayem's saline solution exactly equalling in amount the blood withdrawn. P. K. Pel,¹⁵ director of the Medical Clinic at Amsterdam, advocates venesection in severe dyspnea and cyanosis, and believes that it may often save life. Sir Hermann Weber¹⁶ believes the popular prejudice against bleeding in moderation to be unfounded. Professor Hermann Eichhorst states that venesection is still indicated for the pulmon-

ary edema of pneumonia, and asserts that he has saved many patients from a suffocative death by a timely resort to it. The change for the better occurs so suddenly that no one can doubt the relation between cause and effect. Eichhorst is of the opinion as a consultant that many physicians are altogether too timid about resorting to the method. Even in the case of drunkards or old persons, it may under certain circumstances be safely performed.

H. F. Williams⁴ recommends venesection in robust persons, 10 or 15 ounces of blood being removed from the general circulation to relieve an overburdened heart. William Porter¹⁷ goes so far as to order venesection as soon as the diagnosis is well established; that is, within four days at the farthest from the initial chill.

It is the present writer's opinion, based on a careful study of the literature, as well as from his own experience, that the special indications for venesection are as follows:

Sthenic type of the disease in a robust, full-blooded person and in an early stage.

The presence of a forcibly or violently acting heart with accentuation of the pulmonary second sound.

Dyspnea, with a sense of suffocation and beginning cyanosis of the face.

These indications do not arise often, but when they do occur, the practitioner should be able to meet them by this method, the swiftest and most surely effective at the command of medical science. The amount withdrawn is not to be gauged by drams or ounces, but by the effect produced upon the heart's action and the respiration which, if favorable, will be practically instantaneous. As a rule it is safe to abstract as much as 20 ounces in an average-sized adult patient, although in many cases half that quantity will be sufficient.

On Arterial Sedatives.—A strong feeling has undoubtedly arisen in the medical world against the indiscriminate use of arterial and cardiac sedatives. Eichhorst¹ strongly decries the use of veratrum viride and tartar emetic, which formerly possessed such an extensive vogue. The latter drug appears to have become all but obsolete. So able an observer as Hare,⁶ however, still recommends the use of veratrum viride in sthenic cases in 3 minim doses at 15 minute intervals, along with sufficient Dover's powder to lessen painful cough and increase diaphoresis. Such treatment should be continued only during the first 12 hours.

Dr. Melvin,¹⁸ of Colorado, states that country doctors throughout the West still adhere to veratrum viride, believing that it will hasten the crisis and shorten the course of the disease. Walton⁸ recommends 2 to 4 minims of tincture of veratrum viride every 2 hours, or oftener, watching the effect on the pulse and gradually bringing it down to 70 or 80 per minute. Williams⁴ believes in the administration of aconite in small doses alternately with bryonia alba for sthenic cases, while Herman Weber still maintains that small doses of antimony may be beneficial. C. Z. Weber¹⁹ also recommends antimony, as well as aconite and veratrum viride, under certain circumstances.

It will thus be seen that this plan of medication still has friends. Most practitioners, however, recognize the danger of remedies which depress the power of the heart's action, and it is not to be doubted that arterial sedatives are used with much less freedom than formerly. It is the author's opinion that the advantages claimed for these agents may be obtained with

much greater safety and with equal effectiveness by the persistent use of cold sponge-baths and ice-bags.

On the Use of Calomel and other Purges.—It was customary at one time to begin the treatment of pneumonia, as a matter of routine, with free purgation, and the mild chlorid of mercury was the agent generally employed for this purpose. No recent writer, however, seems to endorse this plan. Cathartics are given in accordance with the requirements of the individual case. As a rule, however, calomel is still the purgative employed when such treatment is required.

On Antipyretics.—The use of internal antipyretics is mentioned by almost all the writers of the year, but only to be condemned. Eichhorst¹ is the only author of prominence who countenances their use in pneumonia. This writer, who is opposed to the use of cold baths, still endorses the exhibition of phenacetin. Quinin is no longer used for its antipyretic effect, although several writers mention it in general terms as being useful. (*Vide* Raw.⁷)

On the Use of Opiates.—Regarding the employment of opiates in pneumonia, the profession is still at variance. Wilks¹¹ states that he is satisfied when he sees a patient taking a saline cathartic, to be followed by a 5 grain Dover's powder every 4 hours. Dreschfeld¹² advises morphia for insomnia until the appearance of expectoration, when it may become dangerous. A. de Winter Baker²⁰ is enthusiastic for the use of Dover's powders in doses of 5 grains every 4 hours. Eichhorst¹ states that opiates should not be given as a rule. The suppression of cough and secretion and the resulting stasis in the bronchi may place the patient in danger of suffocation. Especially to be avoided are hypodermics of morphia for pleuritic pain which may be controlled by wet or dry cupping or local applications.

In the face of the rather contradictory evidence regarding the use of opiates, it would appear to be a good practice to withhold them until positive indications in the way of loss of sleep, severe pain, or intense nervousness, makes their exhibition necessary.

On the Use of Alcohol.—The best sense of the profession at the present day is not in favor of the routine use of alcohol in pneumonia. Yet all writers who mention it admit its use under proper conditions. Michel¹⁴ believes it is almost always indicated in alcoholic subjects. According to Eichhorst,¹ it should be exhibited only to such patients as require a promptly acting stimulant to the heart and perhaps to the nervous system. Hence it is indicated, as a rule, only in the elderly. In youth, alcohol should be administered only to drunkards, for if the stimulant in habitual use be withdrawn, we have to fear both heart failure and delirium tremens. The antithermic influence of alcohol is not worth considering. Pel¹⁵ is of the opinion that in typical cases there is almost always cardiac weakness. Alcohol is then usually urgently indicated, and often saves life. J. M. Allen²¹ gives no alcohol, while Walton⁵ advocates it when the first cardiac sound becomes weak.

Gilman Thompson,²² in his recent work on the Practice of Medicine, recommends the use of alcohol when the pulse begins to fail or increases in frequency to 120 or over. He advises 10 to 20 ounces in 24 hours. Osler,²³ however, states that 2 or 3 ounces of whisky in the 24 hours constitute a sufficient dose in ordinary cases. Broadbent,⁸ with his usual felicity of expression, states that stimulants are rarely necessary but often useful, and should be reserved until their use is indicated. It does not appear that the carbonate of

ammonia is prescribed as much as formerly. It is mentioned in a casual way by several writers, but is usually omitted from consideration. It is the writer's own opinion that this preparation should not be given unless the expectoration is exceedingly viscid, tenacious, and difficult to raise.

Digitalis and the Cardiac Tonics.—There is still much difference of opinion relating to the value of digitalis in pneumonia, but the weight of recent experience offers but little encouragement to its use. Michel¹⁴ is opposed to its employment in pneumonia. He states that by its use we but add further poison to the already toxemic circulation. There appears to be no proof of Landouzy's claim that digitalis is an antidote to the pneumococcus. Michel¹⁴ prefers the use of caffeine when a heart tonic is required. Eichhorst¹ also gives preference to caffeine. He has never been able to convince himself that digitalis exerts any influence whatever on the inflammatory process, although it had been regarded by Traube and his followers as almost a specific.

Eichhorst¹ also recommends the hypodermic injection of camphorated oil hourly or half-hourly in cases where cardiac weakness is extreme. Pel¹⁵ informs us that camphor is the most trustworthy analeptic known to medical science. In cases where life is threatened from failure of the heart, it may administered in large amount subcutaneously with ether. He believes that life may often be saved by this means.

Raw⁷ has very little use for digitalis in pneumonia. In case of rapid heart with a quick, soft, irregular pulse, it sometimes does good in large doses—say 15 or 20 minims of the tincture every two hours until two drams are taken; or $\frac{1}{30}$ or $\frac{1}{20}$ of a grain of digitalis may be given hypodermically to tide the patient over a critical period. Hare⁶ considers digitalis the best circulatory stimulant, but it often fails because of high fever. If the latter is reduced by hydrotherapy, digitalis is most efficient. Response to the drug is so slow that 10 or 12 minims may be given hypodermically, and so lasting that 12 to 24 hours may elapse before repetition is necessary.

All writers mention the use of strychnia in favorable terms. It may probably be regarded as our most valuable cardiac tonic in pneumonia. Perhaps the only contraindication to its use is a state of high nervous tension with active delirium. Nitroglycerin is recommended by several writers as a cardiac tonic in pneumonia in the one condition of high peripheral tension. Its use is not advised with a great deal of confidence by recent authors.

On Oxygen Inhalations.—The use of oxygen inhalations is endorsed by some recent medical writers, and stated to be useless by others. It is admitted to be safe by all. Salinger²⁴ recommends its use for 15 minutes every 2 or 3 hours when actual dyspnea is present. Broadbent⁸ states that inhalations of oxygen are of direct benefit when the face is livid and the lips blue, and with strychnia and stimulants, may be instrumental in saving life. Raw⁷ states that his experience with oxygen has been, on the whole, rather disappointing. No recent author speaks very enthusiastically of the remedy. One gains the impression from a perusal of recent literature, that the chief advantage of oxygen inhalations is in impressing upon the patient's friends that everything possible is being done to effect relief. One well-known consultant states that he generally despairs of the patient's life on seeing an oxygen cylinder by the bedside of a pneumonia patient to whom he is called.

On the Use of Saline Infusions.—No striking contribution to this subject is found in recent literature. The method is adverted to by several writers, but they offer no additions to our knowledge. William Ewart and Beaumont Percival²⁵ employed a saline infusion with rather disappointing results. The cases reported, however, were exceptionally severe and the patients were perhaps incapable of recovery under any method of treatment. They regard the results as warranting a further trial of the method in cases with anxious prognosis.

On Specific Medication.—In a paper²⁶ read before this society at its last meeting, the author considered at some length a scheme of medication based upon the discovery of the pathogenic microorganism of pneumonia. This plan of treatment embraces two separate and distinct methods of therapeutic procedure, as follows :

1. The administration by the stomach of certain drugs tending to destroy the pneumococcus by rendering the blood an unfit medium for its culture.

2. The introduction into the patient's body of an animal serum tending to neutralize the toxic influence of the products of bacillary life. In his former paper the writer presented an outline of what had been accomplished by this scheme of treatment up to that date. During the year which has elapsed it would appear that no great progress has been made in the direction of a specific drug treatment directed against the pneumococcus. Several contributions appear, but they do not embrace a large number of cases and their results are consequently not of special significance. W. O. Bridges²⁷ reports 2 cases of acute lobar pneumonia successfully treated with sodium salicylate, 15 grains every two hours, and 6 successful cases treated with guaiacol carbonate, in doses of 8, 10, and 12 grains every two hours.

J. M. Allen² advocates the use of sodium salicylate in 15-grain doses with milk of magnesia every four hours. He states that the number of pneumococci in the blood and sputum were markedly diminished during its exhibition.

Dr. Chas. F. Stokes²⁸ advocates the use of creosotal in accordance with Dr. Andrew H. Smith's suggestions. He administers this substance with apparently good effect in doses of 12 minims every two hours.

Caccianiga³⁷ advises the internal use of silver salts in the specific treatment of pneumonia, and reports the results in 112 cases treated in this way. Two and one-half to three grains in pill form are given in the 24 hours, or the drug may be administered suspended in mucilage. Under this method the mortality-rate was 17%, whereas under other forms of treatment a death-rate of 28% was observed. Of 47 sporadic cases only 3 died.

Comini also successfully treated 5 cases with silver salts. A sixth case treated by other methods died. These reports, while somewhat meager, are on the whole quite encouraging and tend to stimulate further experiment in this direction.

On the Use of Antipneumotoxin.—The progress of serumtherapy in acute lobar pneumonia cannot be said to have been particularly brilliant during the year 1900. A singular dearth of activity is apparent in France and Germany, the two countries to which we naturally turn for advanced information in this department. A number of tests have been made both with cultures prepared from the blood of pneumonia patients and with animal

serum, and several clinical reports are found in the literature of the year, but the net result appears to leave us about where we were one year ago. Clinical experience has been too meager to allow of any positive deductions being made. Further than this, no apparent progress has been made in standardizing the antitoxic serum, and it is impossible up to the present time to secure a preparation possessing any positive stability.

Chas. B. Canby⁸⁰ publishes an account of the use of Pane's serum in 3 cases. The results in these cases appeared to demonstrate a high degree of value in the preparation, each case being followed by rapid recovery.

J. C. Wilson³¹ considers in detail the subject of serum-therapy in pneumonia, and reports 18 cases treated with McFarland's antipneumococcic serum in the German Hospital of Philadelphia. Of the 18 cases, 4, or 22 %, died. Three of the fatal cases were alcoholic, while in the fourth the history in this respect was unknown. The duration of the attack in the serum cases was 5 to 14 days. Defervescence usually took place by crisis or rapid lysis. The serum was administered in all cases hypodermically, the total quantity varying from 20 cc. to 460 cc. The immediate effects were more marked and more favorable in cases in which recently drawn serum was used than in those in which it had been drawn for a longer period. They consisted in general of a lowering of the pulse-rate, mitigation of the pain, and a tendency to drowsiness. No results could be attributed to the tri-kresol in the serum.

Dr. McFarland, in his discussion of Wilson's paper, stated that the serum was very difficult to cultivate and its nature uncertain. It might be antitoxic or antimicrobial, but was probably both. Alexander Lambert,²² however, states that the antipneumotoxic serum is not bactericidal but bacteriolytic. He used a horse-serum by subcutaneous injection in 12 cases with a result of 9 recoveries and 3 deaths. It seemed to cause a slight reduction of temperature and improvement in the pulse, but did not bring on a crisis in any case. In two alcoholic cases the serum had absolutely no effect. He had not persisted in the use of the preparation because he had been unable to see that it shortened the disease or held in check the pneumonic process. Antonio Fanoni²³ reports 6 grave cases cured with antipneumotoxic serum. In a subsequent communication²⁴ the same writer states that he has successfully treated 9 additional cases by the same means. Several other writers report isolated cases treated with the serum, but their results add very little to our stock of knowledge on the subject. The study of antipneumotoxin is still in an elementary phase of development, and we must await further progress before expressing positive opinions as to its value.

PERIODICAL INSANITY.*

By A. R. DEFENDORF, M.D.,

Connecticut Hospital for Insane, Middletown, Conn.

PERIODICITY in mental diseases has been recognized from earliest times. The ancients supposed it to depend upon the phases of the moon. Later it was associated with atmospheric conditions. At the time when psychiatry came to be recognized as a branch of medical science, it was a generally accepted fact that all forms of insanity tended to recur, which belief is held by some alienists even to this day. Later psychiatrists began to recognize that only certain cases of insanity showed a recurrence, each time exhibiting similar symptoms. These were divided into two groups, periodical mania and periodical melancholia, according as they presented symptoms of excitement or depression. Falret and Baillarger next called attention to a very small number of cases, originating from the same groups, mania and melancholia, which they called *folie circulaire*. It comprised cases in which the periodicity was characterized by a regular alternation between the mania and the melancholia, with perhaps a short interval of lucidity.

More recently many psychiatrists have assigned the name periodical insanity to a definite group, which they divide into periodical mania, periodical melancholia, and circular insanity.

Spitzka says of this group: "Periodical insanity is characterized by recurrence of mental disorder at more or less regular intervals; the attacks being separated by periods during which the patients present a state of apparent mental soundness."

Krafft-Ebing presents a clearer and more definite picture of this group of psychoses, which he describes as being characterized by anomalies of the emotions, formal disturbance of thought, accompanied by appropriate actions with less pronounced delusion-formation and infrequent hallucinations. He includes in his periodical psychoses, besides the periodical mania, periodical melancholia, and circular insanity, dipsomania, abnormal sexual impulses, and menstrual insanity.

Finally Kraepelin has given the most complete and definite description of this form under the name of manic-depressive insanity, assigning to it fundamental

symptoms which serve to differentiate the disease picture at the very onset.

While the tendency to recognize periodical insanity as a distinct disease has been most marked among the German and French psychiatrists, the English and American writers have paid little attention to it. Yet most institutions in America have for some time preserved a place in the classification of their cases for those which show a periodicity. They have been variously called periodical mania, periodical melancholia, recurrent mania, recurrent melancholia, recurrent insanity, and circular insanity. Almost all of the institutions have recognized periodical mania; several circular insanity; a few periodical melancholia, but only a very few have noticed that close relationship existing between these different groups, which warrants their being considered as one form of mental disease.

The examination of the records of the Connecticut Hospital for the Insane for the year 1899 shows that 15% of the admissions, which numbered 426, were cases of periodical insanity. Of these over two-thirds were patients who had suffered from more than one attack. The records of the Worcester Insane Hospital, where the writer spent two years, show that for the year 1898, 14% of the admissions, amounting here to 488, were cases of periodical insanity. Of these almost two-thirds were suffering from the second or later attacks. The records for the same hospital for the year 1899 give 12% of the 548 admissions. The admissions at the McLean Hospital for the year ending October, 1899, show over 23% of the cases to be suffering from this form of insanity. The records of these institutions place this disease in point of numbers second only to dementia praecox.

Periodical insanity may be described as a mental disorder which recurs at intervals throughout the life of the individual. The individual attacks, which appear in one of three forms, the maniacal, depressive, or mixed, are characterized by a sufficiently definite symptomatology to distinguish them from other forms of mental disease. Your attention is called first to the symptomatology of the maniacal, depressive, and mixed forms, the citation of cases illustrating the first two, the etiology, the course, prognosis, and differential diagnosis.

In the maniacal form the most prominent symptom is found in the psychomotor sphere. There is an increased facility in the cerebral centers for the translation of stimuli into action, giving rise clinically to what may be called a pressure of activity. Every impulse immediately leads to action. The patients cannot remain quiet, are constantly in motion, go from one thing to another, open and close windows, overturn furniture, dance about, laugh and sing. When the condition is very pronounced, the impulses for action crowd upon each other so rapidly that they are unable to accomplish anything coherently. It is especially noticeable in speech. The pressure of speech is so strong that it is impossible for them to remain silent. The transfer of word concepts into movements of speech is greatly facilitated, so much so that the internal associations of ideas give way in the direction of the train of thought to the purely external associations, and we have instead of coherent sentences a flight of ideas, and phrases abounding in sound associations. The following is an example: "Neatness of feet don't win feet, but feet win the neatness of men. Run, don't run west, but west runs east. I like west strawber-

* Read before the New York Neurological Society, October 2, 1900.

ries best." The same is noted in attempts at writing. Single sentences, or phrases, may be well started, but they are soon resolved into a senseless enumeration of catch phrases, bits of slang and rhymes. In connection with this intense psychomotor restlessness, it is a striking fact that there is a great diminution of the sense of fatigue. The patients exhibit no signs of fatigue after weeks or months of incessant motion. A certain insensibility to pain, heat and cold is part of the same condition.

In the field of apprehension and comprehension there is more or less disturbance. This is not noticeable in the lightest forms. The greatly increased distractibility of attention is accountable in part for this. Every striking sense perception forces itself upon the patients so strongly that they respond immediately. While speaking of one subject, a sound caught up from the surroundings distracts them and leads into a different train of thought. In this way they lose their power to choose and arrange correctly external impressions.

It is one of the striking features that, associated with great motor restlessness and incoherence of thought, the consciousness is mostly unclouded. The patients continue well oriented as to place, persons and time. Their replies may not clearly demonstrate this, but a careful observation of the actions and remarks indicate that they are acquainted with their surroundings. In the extreme maniacal condition, called delirious mania, the consciousness regularly becomes clouded, but even here one is frequently surprised by their clear apprehension.

The disturbance in the association of ideas is another prominent symptom. The patients are quite unable to follow out any definite line of thought. They leap suddenly from one thought to another. Their remarks show a strong tendency to become overburdened with details which sooner or later will quite divert them from the original thought. The associations of ideas which are common to the everyday life are the ones which play a prominent role in their numerous digressions and incoherent statements. The patients are rich in words, not in ideas.

Hallucinations are rare. Likewise delusion formation plays an unimportant role. Delusions when present are transitory, unstable, and have little bearing upon the actions. They are mostly expansive, occasionally depressive, and when related are often embellished with numerous fabrications.

These patients very often show some insight into their mental condition. They will say, "I am crazy, I know I am crazy," but they rarely appreciate the necessity for their confinement. In emotional attitude the patients are happy, contented, and exhibit a feeling of well-being. They laugh, sing, and joke, and are satisfied with their environment. But more characteristic are their rapid and sudden changes of emotional attitude; in the midst of joy and happiness, they temporarily may become tearful, complaining and abusive.

In the depressive forms, the most characteristic symptom common to all is the psychomotor retardation, which stands in contrast to the psychomotor pressure of activity of the maniacal forms. The translation of sensory stimuli into motor impulses is very slow—is retarded—and in the most pronounced cases it is entirely lacking, giving rise to the condition of stupor. In the mildest forms it appears only as a deficiency in the power to carry out that which has been determined upon. They recognize the necessity to

perform a certain act, they determine to do it, but lack the power. Simple movements, such as walking and talking, are performed very slowly and without energy. The condition may become so pronounced that there is abolition of expression, and inability to move, to leave their beds, and to attend to the calls of nature, or even to utter a word, presenting the picture of stupor.

The association of ideas undergoes a marked change in that it also shows retardation. The patients are silent because they have nothing to say. In marked contrast to the maniacal states in which there is profuse production, here there is an utter dearth. Their responses to simple questions are uttered slowly, in low tones, and are monosyllabic, indicating a lack of reflection and a poverty of ideas.

The emotional attitude is uniformly one of depression, despair, gloom, and anxiety. The field of apprehension does not show much disturbance except in the more marked cases where stupor prevails, then there is cloudiness of consciousness with disorientation, or a condition of dreamy confusion. Hallucinations and delusions are prominent features. The hallucinations are mostly of hearing, and of a depressive character. The delusions are apt to be uniformly persistent and stable, and are accompanied by a corresponding emotional attitude, which is more or less constant and pronounced. The delusions at first may be only of reference, but later they develop into ideas of persecution and self-accusations. Delusions of a somatic character are also apt to prevail.

The mixed form comprises a mixture of these two. Usually one type predominates over the other, giving rise to two forms, the maniacal stupor, where the depressive symptoms are the most prominent, and the stuporous mania, where the maniacal symptoms are the most marked. In the former the patients remain the greater part of the time in a stuporous condition with marked psychomotor retardation. We have, interrupting the condition for short periods, a typical maniacal state with pressure of activity, flight of ideas, and happy exhilarating attitude. These patients suddenly jump up from their seat or bed and waltz about the room, singing, perhaps overturning some fellow-patient in jest, and after a few minutes, or hours, return to their previous stuporous condition.

In the condition of stuporous mania, the typical maniacal symptoms are interrupted by short periods of depression with retardation.

As illustrative of the disease, I have selected two cases, one of each of the maniacal and the depressive forms.

CASE I.—J. H., the patient, is a woman 19 years of age. Her mother is said to be insane. She has a good personal history. At 18 years of age, April, 1899, following an attack of influenza, she became despondent, lost all activity, showed retardation in movements and speech; as expressed by her sister, she would remain seated, unoccupied, and in one place for the entire day, and barely would speak a word. She expressed no delusions or hallucinations. After 3 months she slowly regained her activity, began to sew and engage in housework. She then explained her condition by saying that she had felt all the time as if a heavy cloud had settled over her, which hindered her from thinking, moving or speaking. The consciousness was clear. In the fourth and fifth months she would say that the burden was lifting and that she was feeling like her old self.

She was able to return to her shop-work by November, 1899, where she was steadily engaged until April 9, 1900. She arose that morning saying that she had had a dream, in

which she saw a man who had laid commands upon her and had threatened to kill her unless she obeyed. She immediately developed great psychomotor activity, singing, dancing, talking incessantly, and displaying many impulsive actions. She was brought to the hospital on the fourth day, at which time she showed the greatest possible pressure of activity; her movements were incessant, of great variety, and performed with much energy. She would rush down the corridor, shouting at the top of her voice, suddenly stopping to waltz gracefully a few times, ending at the door, which she would pound vigorously as an accompaniment to a Bowery song, then turn about and commence a declamation abounding in sound associations and accompanied by the wildest gestures. Suddenly she would bend on her knees in an attitude of prayer, singing softly a couple of bars, and then burst out in boisterous laughter, making a dash at the clothing of the nurse, attempting to tear it from her. When forcibly held in a seat, her hands, feet and head were in constant motion, sometimes in rhythm to a song, at others beating a tattoo. It is characteristic of these movements that they are purposeless and never show stereotypy, are easy and sometimes graceful, but are never constrained, which points serve to differentiate them from those in other forms of psychoses. The attention cannot be attracted except by persistent or forcible speech, sometimes accompanied by a little shaking of the shoulder, when she answers pertinently in monosyllables, but is sure to run off immediately into irrelevant remarks, following the line of formal associations. Frequently a bright object held before her leads quickly to another train of thought, which may be just as abruptly distracted before half expressed. The content of her thought is rich in words, but poor in ideas. It centers about her former experiences with various friends, contains many proper names, common phrases, slang and rhymes. That she is keen of perception at times is indicated by occasional remarks which demonstrate that she knows something about where she is and those associated with her. Her emotional attitude changes rapidly; at one moment she is laughing heartily over an unattractive picture in a newspaper, trying amiably to elicit the physician's pleasure; at the next she suddenly assumes the attitude of defiance, cursing him roundly, and tries to relieve him of some of his clothing. At times she seems to have hallucinations of hearing and appears to address unseen acquaintances. Only occasionally does she express depressive or expansive delusions, which are purely transitory and in no way influence her actions. The reflexes are exaggerated. Physically the sleep is very much disturbed, the appetite is excellent, and she maintains her normal weight in spite of her greatly increased activity. This condition continued without abatement or change for four months, at which time the great activity began to disappear and the train of thought became more coherent. Since then improvement has been gradual. At the present time—after 7 months—there still remains volubility, and some excessive activity and business about trifles; otherwise the attitude and coherence of thought are quite normal.

CASE 2.—M. F., a patient now 26 years of age with good family and personal history. At 22 years, while out at service, without any apparent cause, she suddenly became despondent, lost interest in her work, took sparingly of her food, became dull; in movements gave evidence of retardation, was slow, sluggish, spoke at first in low tones, and in reply to questions was monosyllabic.

She did not express delusions or give evidence of any hallucinations. The consciousness at first was clouded. In the course of five days the retardation had so far increased that she remained in bed, paying no heed to the calls of nature, and becoming almost mute. Once or twice she exhibited impulsive movements, when she attempted to strangle herself, and threw her clothing out of the window.

Finally, after 2 weeks, she refused food for 1 week. After this she continued profoundly depressed. Although absolutely silent she would carry out the directions of the nurse, showing the preservation of the power of apperception, but her movements were exceedingly slow and without energy. After 5 months she became a little more active and did some mending, but she still continued silent. In the following month she was able to work regularly in the dining-room, though inclined to be reticent and diffident. She never expressed any hallucinations or delusions. In 8 months more she left the hospital completely recovered,

with clear insight and fair memory for events of the psychosis.

She immediately reentered service and continued in that employment until 25 years of age, when she again suddenly became despondent without evident external cause. She became listless in her housework, and lacked initiative. In carrying out directions she required repeated prompting. Finally, in 5 days she became so sluggish that she would remain unmoved in one place for hours. In the third week she expressed hallucinations of hearing, saying that she heard some one about her repeating that she was bad, and in accordance with this idea she would frequently move her hand as if to brush some one away. She was able to recognize her former acquaintances, but was unable to speak to them. In answer to questions she was monosyllabic, or would simply nod or shake her head. Her answers were much delayed, sometimes requiring several seconds for utterance, and meanwhile the countenance would give evidence of effort. For a few days at a time she would exhibit some restlessness when she would walk slowly up and down the day room fidgeting with her hands. On a few occasions she was heard to mutter to herself, "Oh, let me off the hall, the sinners are after me, let me die! I have caused all sin, let me die, so that I can stop thinking!" but most of the time, for 9 months, she sat quietly by herself unemployed, perfectly mute, with dejected countenance, not even expressing delusions when questioned. The orientation was undisturbed, she knew perfectly the place, those about her, and the day of the week and month.

She then gradually became interested in ward work and would converse in low tones to nurses, but not until 4 months later was she able to overcome all retardation, to speak out in natural tones, and to work with perfect freedom.

During the attack there was some tendency toward constipation and a very moderate loss of weight.

The most prominent etiological factor in this disease is the defective heredity, which is found in from 70–80% of cases. Occasionally the parents have suffered from the same form of mental disease. It often happens that the first attack has an exciting cause; this is especially so in women when it appears during pregnancy or the puerperium.

Other exciting causes are shock, acute diseases, and mental strain. More frequently the second and succeeding attacks occur independently of an external cause. It occasionally happens in women that when the first attack appears during puerperium or pregnancy, the succeeding attacks recur with each childbirth, and almost always continue to recur after the climacteric. The first attack in over one-half of the cases appears before the twenty-fifth year. Less than 10% appear after the fortieth year. The first attack is more often of the depressive form. Succeeding attacks are likely to be of the same type as the first, but it very rarely happens that all the attacks are of the same form. At some time or other during the life of the patient who has been suffering from recurrent attacks of one form, an attack of the other form is very apt to appear. The interval between the individual attacks varies. In 4–5% of cases the attacks pass directly from one into another, alternating between the maniacal and the depressive forms, presenting the picture of *folie circulaire*. In the other cases (95%) the intervals vary from a few weeks to many years. We have no means of judging whether the intervals are to be short or extended. The attacks are, however, more frequent between the ages of 15–25, and again during the climacteric.

It sometimes happens that only one attack occurs during life, but when there is but one attack it differs in no essential particular from the attacks recurring as many as three times annually. As the attacks are repeated, the lucid interval tends to shorten,

and the duration of the attacks to lengthen. The patients do not suffer from mental deterioration except when the attacks have been long, frequent and severe. During the lucid intervals mental faculties are retained. In the few cases when the attacks have been long, frequent, and severe, there is a very mild degree of mental deterioration, indicated by a certain amount of constraint, a lack of independence in action, a tendency to be morose, unusual susceptibility to fatigue, sleepiness, and a diminished capacity for work, or, on the other hand, there may be irritability, self-consciousness, and instability.

The prognosis of the psychosis is bad, in view of the tendency to recurrence, but more favorable when one considers the recovery from the individual attacks, and the prospect for lucid intervals of varying length, during which time they are capable of caring for families or returning to business.

During the height of the disease, or in the extreme maniacal and depressive conditions, death may occur from exhaustion, or in consequence of self-inflicted injuries.

One of the great advantages of being able to recognize this form of insanity at the onset of the disease, is the comparative certainty in forecasting the future course. For instance, in the case of the young woman who in April, 1899, developed the depressive form of periodical insanity, lasting five months, then enjoyed a lucid interval of seven months, when she suddenly developed an attack of the maniacal form, we immediately offer a good prognosis for the present attack, with a reservation that 5% of cases become circular. But we emphasize the fact that she probably will have other attacks at varying intervals, and furthermore that she will never suffer from great mental deterioration. This prognosis, which we are able to outline with a great deal of certainty, aids in the prevention of marriage and the excessive engagement in business, both of which patients are very apt to do in spite of the moral restriction placed upon them by the physician.

That periodical insanity with such a definite symptomatology, course and outcome, has failed of recognition, except by its periodicity, is evidenced by the fact that those who describe it say that it can be recognized only in this way.

Spitzka says that "the deliria if present are apt to be of a reasoning character, while moral or affective perversion and certain propensities and impulses not ordinarily found in the simple insanities, serve to indicate the character of the disorder. Aside from these signs it is only the history of the case revealing the periodical recurrence of similar attacks, which serves to justify a diagnosis that the disorder is probably a periodical one."

Chapin notes* that the actions in the recurrent insanity are not unlike those described as characterizing mania or melancholia in its various manifestations.

Kirchhoff says in his description of periodical insanity, especially in reference to the periodical mania, that diagnostic doubt can only be removed by the repetition of the attacks.

Berkley says "the diagnosis of 'periodical melancholia' can only be made out with certainty when a recurrence has taken place." Of circular insanity, he says that the diagnosis "can only be made upon the basis of an indubitable history of the disease and of the family record, or after observation for months or years."

Periodical insanity is distinguished from dementia

praecox by its more rapid onset, absence of mental deterioration, and the periodicity of the course. The depressive forms of periodical insanity are distinguished from the conditions of depression encountered in dementia praecox by the existence of retardation, the uniformity of the emotional attitude, the continuous presence of depressive delusions. The stuporous state in the catatonic form of dementia praecox is distinguished by negativism, muscular tension and the tendency to constrained positions. The conditions of excitement which occur in dementia praecox differ from the maniacal forms of the periodical insanity by the absence of pressure of activity and flight of ideas with formal associations, and by the presence of delusions and hallucinations. The latter if present in the maniacal states are infrequent, unstable, and have but little bearing upon the actions.

In conclusion we may say that

a. periodical insanity is a mental disease characterized by a definite symptomatology, course and outcome.

b. It, in point of numbers, is one of the most prominent psychoses.

c. The symptoms are sufficiently characterized to permit a differentiation from other forms of mental disease in the first attack,

d. and allow the forecast of the whole course of the disease, *i. e.*,

e. recurrence of attacks throughout the life of the individual, mostly of the character of the first,

f. with lucid intervals of varying length from weeks to years, except in very small percentage of cases,

g. without a tendency to mental deterioration, except in cases where the attacks have been long, frequent, and severe, and even then it is of a light grade.

MEDICAL EXAMINATION OF SCHOOL CHILDREN.*

By EDWARD M. GREENE, M.D.

Medical Inspector of Schools, Boston, Mass.

THE first city in this country, or abroad, to establish a system of daily medical inspection in all the public schools was Boston. Since then similar methods of inspection have been adopted in New York City, Chicago, and in most of the large cities, as well as in many of the smaller towns. Within a few years we may expect to see some method of medical inspection in general used throughout the country. The important questions are how comprehensive and searching an inspection is desirable, or practicable, and how to organize and conduct the work in the most efficient manner.

I can probably serve you best by giving you the details of the system in use in Boston, and the results of my own observation and experience as a Medical Inspector for the past 7 years.

Medical inspection of schools, both public and parochial, was begun in Boston in the fall of 1894 and was secured only as the result of 4 years of persistent effort on the part of the efficient and progressive chairman of the Boston Board of Health, Dr. Samuel H. Durgin. The immediate occasion which made his appeals successful was the unusual prevalence of diphtheria in Boston during the year 1894.

The system of inspection is under the control of the Board of Health. The School Committee cooperates

* Paper read at the meeting of the Providence Medical Association on February 4, 1901.

cordially in the work, by giving permission for inspectors to enter the school buildings and examine pupils, and by directing teachers to watch for cases of illness and to bring them to the notice of the inspectors.

The masters and teachers appreciate the fact that this work is beneficial to themselves as well as to the pupils, and are anxious to cooperate in carrying it out. The parents see, with approval, that their children are safeguarded from danger, and from the general public nothing has been heard but commendation.

Inspectors are generally selected from the younger men in general practice, as they have most time to devote to the work. Many of them have been hospital internes. They must be interested in the work, discreet, and tactful, and it is desirable that they should live in the locality of the schools assigned to them. There have always been some homeopathic doctors among the Boston inspectors. The work has nothing to do with therapeutic systems, but requires only the ability to make accurate diagnosis. In establishing a work of this kind it is important to have the support of the whole community. Women physicians have not yet been appointed in Boston, but I am told they have been in New York. If otherwise qualified they would make good inspectors, especially in the higher schools for girls.

The number of pupils in the public schools of Boston is about 80,000, and there are about 13,000 more in the parochial schools. There are 250 school buildings, and 50 inspectors of schools, each doctor thus having 5 schools and nearly 2,000 children under his care.

The pay of inspectors in Boston is only \$200 a year. Though the salary is small, the position is an honorable one, and likely to increase a young man's reputation though not his practice directly. Children are not allowed to go to his house in connection with school work, and any that he finds ill, are carefully directed to call in their own family physician, or, if poor, directed to a proper hospital.

To maintain faithful and efficient work on the part of the inspectors some central supervision is necessary. A monthly report, filled out on a printed form is required from each inspector. The report contains a list of the different diseases observed, and the number of cases of each disease found in each school. It also records the number of pupils sent home; the number of vaccinations performed, the number of consultations with teachers in regard to such matters as sending children out of school for contagious disease at home, the determining when they may return to school, and giving advice to the teacher on any other subject. On the back of the blank forms there is printed a classified list of the important or common diseases. To secure uniformity and accuracy, the inspectors are requested to use this approved nomenclature in making their reports. Inspectors should familiarize themselves, if necessary, with the symptoms and appearances of all the diseases there mentioned. This involves, among other things, a considerable knowledge of diseases of the skin, which is not always possessed by the general practitioner.

These reports are mailed at the end of each month to the secretary of the Board of Health, who can then form some opinion of the amount and quality of the work done by each inspector. At the end of the year all the reports are tabulated and published in the annual report of the Boston Board of Health.

An association of the medical inspectors has been

formed which holds meetings from time to time, and is presided over by the chairman of the Board of Health. The objects of the association are: to make the men acquainted with each other; to establish an *esprit de corps*; to secure uniformity of decision on questions of school attendance, in order that children of the same family in different schools may be alike excluded, or admitted, after there has been contagious disease at home; to discuss the methods by which the contagion of diphtheria, and similar diseases, may be spread in the schools, the criteria for determining when the danger of contagion is ended, etc. The association has been addressed occasionally by specialists in diseases of the eye, ear, nose, and throat, etc., who have discussed the diseases of those organs which have especial importance in relation to our school work.

Let us now follow the inspector as he makes his daily rounds. He has to deal with teachers as well as pupils. The former receive such instructions in regard to the early symptoms of contagious diseases as helps them to promptly detect suspicious cases, and send them to the inspector for examination. They are taught the importance of having the child's eyes examined when there is a complaint of habitual headache, and the necessity of examination for polypi, or enlarged tonsils, in mouth-breathers, and many other useful things.

The inspector sees only those children to whom his attention is called by a printed slip on which the teacher has filled out the date, name of the child, the number of the school room, and the complaint which the child makes, or the symptoms which the teacher has noticed. These slips are filled out soon after the opening of school, and deposited in a convenient place where the inspector finds them. On his arrival at school, each child is sent out to him for examination. On each child's slip he records his own diagnosis, and his advice in regard to excluding the child from school or not, and any remarks he wishes to make for the information of the teacher. The child hands the slip to the teacher, and the latter sends it to the master, who is obliged to keep these slips on file, thus preserving in each school a record of all the illness that occurs there. An opinion can then be formed in regard to the relative sanitary condition of each building. Questions of drainage, plumbing, heating, and ventilation, are not considered by the medical inspectors, but are referred for investigation to special experts of the Board of Health.

The children who come under our inspection may be divided into two classes: 1. Those who are the subjects of contagious disease, and who must be excluded from school for the benefit of the other children. 2. Those who are suffering from noncontagious though perhaps severe and disabling disease, or who are mentally or physically below the normal standard. Some of this second class may be advised to stay out of school, as in cases of certain acute diseases of the eyes, or ears, ozena (if particularly offensive), spinal caries, epilepsy, etc. A considerable number of children of the first class are found,—those who are suffering with the specific infectious diseases, or with contagious parasitic skin diseases. Some are found among the poorer children, who have returned to school after some unreported illness, for which they have had no physician, and in whose throats the bacilli of diphtheria are sometimes discovered; others are found to be still in the desquamating stage of scarlet fever.

The inspector should always have with him one or

more of the diphtheria culture outfits, which are supplied by the Board of Health, and take a culture from every case of acute pharyngitis, or tonsillitis, which he sees. Many cases of diphtheria can be discovered in no other way. After a culture has been made, the child is sent home to remain until a report has been received from the laboratory on the following day. If a case of contagious disease is discovered the child's books are wrapped up in a bundle and sent to the Board of Health for disinfection or destruction, and the desk and seat are washed by the janitor with a strong solution of corrosive sublimate or formaldehyde.

If more than one contagious disease is found in any room every child is sometimes examined by the inspector. Clinical thermometers are never used, on account of the difficulty of thoroughly disinfecting them. For a tongue depressor a thin, narrow piece of pine wood is used and burned after use, so that nothing is carried from one child's mouth to another's. This is a very important precaution, and has been the means of forestalling criticisms. The practice of having a child use his own finger for a tongue depressor is strongly condemned, in spite of its convenience, as the soiling of the fingers with the secretions of the mouth would greatly increase the danger of spreading the contagion.

The question of excluding children affected with pulmonary tuberculosis has arisen. For the child's own sake, as well as to protect others, we advise the exclusion of such children.

To protect the healthy from the dangers of contagion is hardly more important than to improve the condition of those who are more or less defective physically. Often they may be advised of the measures necessary to make them healthy and vigorous and to greatly improve their capacity for pleasant and profitable study. It has been a great satisfaction to me to have detected numerous cases of previously unsuspected chronic hypertrophy of the tonsils, or of adenoid disease, and to have pointed out to these delicate, chronically ailing children the importance of being carefully treated by experts in diseases of the throat and nose. At my suggestion the teacher often writes a note to the parents explaining the conditions found, and the importance of treatment. The improvement of mind and body that is later observed in these children is remarkable.

Another very important subject which is brought to our attention daily is that of imperfect vision, with its resultant evils of eye-strain, habitual headache, and nervous debility. Such cases are very frequent. When there is no visible lesion; we roughly test the child's ability to read printed matter or figures on the blackboard at normal distances, and if this is not easily done, or if there is habitual headache without other obvious cause, we have the parents advised to take such children to an oculist for expert examination. Many of them go to hospital clinics where, I am sorry to say, they are sometimes turned over to young and incompetent assistants, and return to school wearing improper glasses, and without relief from their unpleasant symptoms. The labor of examining so many cases of errors of refraction proves tedious and uninteresting to the older and abler oculists of the hospital staff. Certainly great good could be accomplished by having a competent oculist make a systematic examination at the school, once at least, of all the children in the grammar school grade. The Boston Board of Health has not yet been able to see its way to having this service performed.

Much has been done in giving advice to individual pupils on the subject of proper clothing, food, exercise, and cleanliness. Inspectors are sometimes invited to address the teachers of their schools on such subjects, and sometimes mothers of younger children have been present to hear such addresses.

A great and salutary lesson in personal cleanliness, and one long remembered, was taught the children a few years ago when a systematic inspection was made of the heads of all the school children in Boston, for the purpose of discovering pediculi capitis. One-half of all the children were found to be infected, more or less, with these parasites, in some cases to a very disgraceful extent. In one of my primary schools, where the pupils were nearly all children of ignorant foreigners recently arrived from the "old country," nine tenths of all the children were found to be infected. The need of proper treatment was so urgent that an exception was made in this one instance to the rule forbidding the giving of prescriptions, and each infected child was given printed directions to buy and properly use a good supply of crude petroleum. Those who were found on subsequent examination to have neglected this advice were promptly excluded from school until they returned clean. Some heart-burning was occasioned among the mothers and children of the better class who were taken by surprise at our diagnosis, but we heard much more of commendation than of criticism. Some amusing incidents occurred. One small boy, ignorant of the object of the examination, told his mother on returning home that the doctor had examined his head, and had told the teacher "there was nothing in it." The fond mother at once entered a violent protest against having her young hopeful put into a class with idiots.

Shower-baths have been put into the basements of some of the recently constructed school buildings, and children are now allowed and sometimes requested to make a systematic use of them during school-hours.

Innumerable other questions may suggest themselves to you in regard to this work, as I have attempted to present only the most important features of the subject.

TETANUS FOLLOWING CLEAN OPERATION WOUNDS.*

By JOSEPH B. BISSELL, M.D.,

of New York.

Visiting Surgeon to Bellevue and St. Vincent's Hospitals.

The sudden advent of symptoms of tetanus after an apparently clean operation, where the wound had united by first intention, without any indication of other infection, is so rare that the following 2 cases seem worthy of consideration; more especially because in both cases the disease went on to a fatal termination.

The operations were months apart. Both took place in St. Vincent's Hospital in New York City. One was operated upon by myself, and the other by my colleague, Dr. John Aspel. One occurred in one building of the hospital, the other in another building. These buildings are at different ends of a city block, only connected with each other by a long corridor. Neither operator was present at the other's operation. There was a separate staff of assistants, as well as nurses. None of the instruments were used in both operations.

* Read before the New York State Medical Society at Albany, January 31, 1901.

The ether was given in both cases by the same physician. The catgut used was prepared and treated in the same room and by the same person, and taken from the same general reservoir in both cases; but the dressings as well as the instruments had been kept in different operating rooms. The above two circumstances are all that the 2 cases have in common. Several hundred other cases before those operations and since have had the same etherizer and the same catgut, and there have been no other cases of tetanus. It would seem fair, therefore, to throw out any suspicion of their complicity in the infection. Both these cases were women, and both were abdominal operations, in a sense.

CASE 1.—P. H., female, 36 years old, German nativity. Family history negative. Her general health had always been of the best. A few years ago she had had some trouble with her teeth, and several had been drawn. She wore a plate of false teeth when she entered the hospital. Had had three children; last child two years ago. All of her labors normal, and children healthy. About six months ago her present condition began. Her symptoms became gradually worse, until upon entering the hospital she had a procidentia uteri to a degree that the os protruded through the vulva. The patient was a well-nourished woman, all her functions and organs normal, except for constipation. On October 29, 1900, she was prepared in the usual way for operation, but as there had been a number of cases in which pus was present in the hospital, special care was taken in the disinfection of the patient and the antiseptic precautions of the surgeons and the dressings. Under ether anesthesia the cervix was dilated and the uterus curetted. As the perineum was somewhat relaxed, a moderate perinorrhaphy was performed. Next a double Alexander operation was performed. The patient came out of the anesthesia in good condition. The operation was rather long, lasting about two hours. The patient ran a normal postoperative course, with the exception that on the fifth day the temperature was a little over 99° F. On the fourth day following the operation the dressings were removed and the wounds in the inguinal region were found united by first intention. The stitches used were catgut in each wound, except in the perineal wound, where one silkworm suture was put in. This was removed, together with the catgut stitches, on the sixth day, when the perineal wound seemed to be united. On the fourteenth day following the operation, the patient complained of stiffness about her jaws and some difficulty in opening her mouth. On the next day the muscular rigidity about the jaws had increased, and she exhibited marked signs of trismus; she also had pain on deglutition as well as a feeling of constricting bands about her throat. Her temperature and pulse were normal. On November 15th, the day following, her general condition was worse and she had an anxious, strained expression in her face. From time to time there was a spasmodic contraction of the facial muscles, exhibiting the symptoms of risus sardonicus. At this time began periodical contractions of the abdominal muscles. Two days later, for the first and only time, until the day before her death, the temperature went to 100½. Her pulse now became much more rapid and she was gradually losing strength. She continued to have convulsive movements of different sets of muscles, principally in the abdominal region and about the face and neck; her pulse at this time running from 112 to 120; her respiration being 24 to 30. On the evening of November 21st her temperature suddenly went to 102½, her pulse 138, respiration 104. When free from her convulsions she had no pain and no other symptoms except that the jaw was very rigidly fixed up to 48 hours before her death. She died on the morning of November 26, of heart failure, her general circulatory condition having weakened perceptibly in the last 24 hours. The treatment consisted of large doses of chloral, bromide, and physostigmine. Twenty grains of the chloral, 15 grains of bromide of soda, and ½ of a grain of physostigmine was given every four hours. It was possible by this means to diminish the convulsive movements very markedly, so that there was no great increase of such symptoms from the beginning of her spasms.

CASE 2.—Patient was a fairly well nourished woman, of about 40 years of age, upon whom the laparotomy was per-

formed on September 6, 1900. The abdominal incision was large and through it a 10½-pound fibroid was removed, together with uterus and adnexæ. There was no complication with the removal. Hemorrhage was controlled and prevented by the use of the angiotribe and heavy, silk ligatures. The abdominal wound was closed by a single layer of deep silkworm-gut sutures. A few superficial sutures of the same material were also taken. Anesthesia lasted 2 hours, and the operation 1 hour and 50 minutes. At its conclusion the patient was in a very good general condition, and experienced practically no shock. After operation the patient did well, and with two exceptions the course was uneventful—the temperature was somewhat irregular, and the bowels somewhat troublesome. On the morning following the operation the temperature was 101°, and from this time on for 8 days it did not go below 100°, but vibrated between this and 102°. This temperature was thought to be due to the condition of the bowels, especially as there was great difficulty in attempting to get intestinal evacuations. Eight and one half days after the operation there was first noticed a slight trismus and a rigidity of the postcervical muscles. This condition grew so rapidly worse that inside of a few hours the jaws were firmly locked, and there was a large accumulation of mucus in the pharynx with great rigidity of the neck muscles. In the afternoon of this day there were two severe spasms lasting about 2 minutes each. There was rather profuse perspiration following the injection of antitoxin which was used at 10 o'clock in the morning; the first symptoms of the tetanus having been noticed at 9 o'clock. Two more injections of 20 cc each were given during the afternoon. The first injection contained 40 cc. Board of Health antitoxin was used. At this time the temperature was 103°, but soon fell to 102°, remaining there until the next morning. On this day, the 15th, the dressings were removed and the wound examined. It was of healthy appearance, and there was no local tenderness. All sutures were removed. The next day, September 16, the patient grew continually and rapidly worse. The muscular rigidity was more marked and the clonic spasms increased in rapidity and duration until they were coming on every half or even quarter of an hour. At first only the face, trunk, and upper extremities were rigid; later the rigidity was general. In addition to the antitoxin, of which 160 cc. were given, chloral and bromid and physostigmine were also used as sedatives. Chloroform inhalations and morphin hypodermatically were also given. The temperature rose and the pulse increased to 105 and 106 respectively, the convulsions getting stronger and the patient getting weaker, until she died of exhaustion on the afternoon of the 16th. During the last hour the patient was semicomatose.

It will be seen that the course of the tetanus was distinctly different in the two cases. In Case No. 1, the disease began and lasted practically without any temperature for 14 days. It began in this patient on the fourteenth day, and death occurred at the end of two weeks. In Case 2, it began on the ninth day and the patient lasted only a little over 24 hours. In the first instance no tetanus antitoxin was used, in the second case it was used subcutaneously in fairly large quantities.

Aside from the sudden and startling appearance of the tetanus, going on to death in one case in a little more than 24 hours, the most interesting feature for discussion are the etiology and the treatment.

Such adjectives as idiopathic, rheumatic, spontaneous, and autoinfectious, to describe the cause of tetanus, are used, I believe, simply to cover up our ignorance and are silly subterfuges unworthy of scientific men. The following facts about tetanus are proven and undisputed:

The disease is caused by a germ, which, with its toxin as well, has been clearly isolated. According to Park, one of the best known American bacteriologists, the tetanus bacillus occurs in nearly all garden soil, superficially and to the depth of several feet, especially

soil which has been manured. It occurs in hay dust, in the intestine of the horse and the cow, and hence in manure, in the mortar of old masonry, in the dust from rooms, barracks and hospitals, in the air, and in the poison used on the arrows of certain savages who obtain it from crab-holes in the swamps. The spores of this bacillus are very resistant, they retain their vitality for months and years in a desiccated condition. The bacillus will grow in the presence of oxygen or of most acids. It takes 3 hours soaking in a 1 to 1000 bichlorid solution to destroy the spore. Carbolic acid in 10% solution will kill it. An exposure of an hour to 80° C. does not affect it. A $\frac{1}{10}$ of 1% HCl solution will destroy it in 5 minutes. The great virulence of this germ is well known. It grows best at 37° C. It does not multiply in the human body, but produces lesions through which absorption takes place at the point of entrance.

The toxin of tetanus, according to the best authorities, has a selective affinity for the cells of nerve-tissue. It acts directly on the substance of the motor ganglia and produces changes in them. In the cases which recover these changes either are not produced, or they cannot be very lasting ones, as but few cases are on record where, after a cure, the results of the muscular spasms remain. Examples of the longevity of the tetanus bacillus are frequent and undisputed. Hermann Kaposi reports a case where the germ entered the body at the time of an accident which occurred 5½ years previous to his operation. The operation developed tetanus and the case terminated fatally. Another case was that of an officer in the German Army who was injured by a bullet passing through the soft parts of the pelvis and injuring the bones. The bullet was removed at some distance from the point of entrance, and both entrance-wound and wound of removal healed kindly. Two and a half years afterwards, following a hard day's exercise in stormy weather, tetanus symptoms developed, and he died on the fifth day. The surgeon who reported this case believes that this exposure to cold, with a tired-out body, had lowered the resistance of the tissues so that the tetanus germ, which had been present and quiescent during these years, was stimulated into activity, and the tetanus infection took place. There was no other exposure to a tetanus germ that could be discovered after a most careful investigation.

Cheeseman reports a case of tetanus coming on 8 months after vaccination. A number of other cases are on record in which the disease developed several months, or even years, after the known exposure to the bacillus. Dupuytren reports a case of tetanus following an operation. At the autopsy it was accidentally discovered that a tiny piece of a whip was embedded in a scar on the body. From this foreign body tetanus cultures were produced. The patient had complained of neuralgic pains in the scar for the past several months.

Morgan reported a case where a splinter, which had caused a neuralgia lasting 2 months, was removed, and rabbits inoculated with it died in a few days of tetanus.

In this country and abroad numerous well-authenticated cases of tetanus are recorded following vaccination, erysipelas injections, and other serum injections. In many of these the time between the introduction of the serum and the development of the tetanus is of varying length. It is not known how long the tetanus bacillus will keep its vitality in living tissues. Why these bacteria should remain quiescent in the body for

days or months, or even years, and then suddenly become active and produce their toxin, is hard to explain. We can, however, surmise that the resistance of the human body to these germs, as well as others, may through some injury to the tissues or depression caused by an operation, a severe cold, or other irritation, become weakened and thus give stimulus to the bacillus to produce its toxin, and the disease occurs.

As to the point of entrance of the poison, the bacilli themselves in all probability do not enter very extensively, at any rate, the human body. They make a lesion, however, through which the toxin is absorbed. Thalmann, in a large number of experiments on animals, proved that the most favorable point for incubation of the tetanus bacillus and of entrance for its poison was the cavity left after the extraction of a tooth; next most infectious were wounds of the nose and mouth. Injections of the tetanus bacillus into the stomach, the intestine and the urethra gave negative results, even when the lining of these organs had been injured or was diseased. If the breathing apparatus was sound and undiseased, no effect was caused by the inhalation of the germs. In one case where catarrhal inflammation was present infection occurred. Diseased tonsils offer a most acceptable road of entrance to the toxin.

For my own cases there are only two possible explanations for the origin of tetanus—either want of proper disinfection against this germ, or a preceding exposure, the bacillus remaining innocuous until excited by the trauma of an operation.

As to the asepsis in my patients: There had been several instances of slight infection in the operative cases in the hospital, and special pains were taken with these cases in order to prevent further infection. The patient, the field of operation, the hands of the operator and his assistants, the instruments and the dressings were carefully prepared and rendered as near aseptic as practicable methods could devise. Other patients were operated upon on that day, the days preceding and the following days under as near as possible the same conditions, and no other case of tetanus developed.

As regards a dormant bacillus, the cases in the literature cited above would seem to prove that such a proposition is possible, and indeed much more probable than that infection took place at the time of operation. In the first case reported by me—that of P. H.—the cavities left by extraction of her teeth several months before may have been the starting point of this disease.

Treatment.—The modern treatment of tetanus resolves itself into two classes—preventive treatment by means of vaccination, and treatment after the disease is present. Preventive treatment should be carried out wherever there are cases of tetanus in the hospital or in the neighborhood of an operation; where there is a history of exposure, however remote, in a given case for operation; or in an accidental wound; in those districts where tetanus is common; or in injuries where the wound has been contaminated with earth in any way. The injection is harmless, if it be a definite and well-prepared antitoxin, and the probability of its success is great. Tizzoni reports two cases infected with a very virulent tetanus culture. Both were students in his laboratory. Antitoxin was used subcutaneously. One, in which it was used on the third day following the infection, had very slight symptoms and recovered. The other case was injected within 24 hours; at the end of 13 days he had slight convulsions of the

muscles of the extremities, and recovered without further symptoms. Bazy, in his surgical clinic, when he thought there were conditions favorable to tetanus, immunized all his cases before operation by injections of the serum. In his 23 cases none had tetanus; while, under exactly similar conditions in the preceding year, not having taken antitetanic precautions, he had four cases. In a tetanus epidemic in Prague, at one of the obstetric clinics, for nearly a year all antitoxic measures failed to prevent the appearance of new cases. After preventive vaccination was used in every woman before confinement, there were no cases; while in the neighboring clinics there were numerous instances.

When tetanus is present, it can be treated in three ways: By medicines, usually in the form of sedatives; by injections of antitoxin; and by a combination of the two methods. A fourth way is by the injection of some antiseptic solution, such as bichlorid of mercury or carbolic acid, or by extractives, such as brain emulsion; these substances, however, have not proved satisfactory, and in several recorded cases this method has done positive harm. Inasmuch as the antitoxin affects at once the tetanus poison in the circulation and destroys it as rapidly as it arrives, it is unnecessary to reopen healed wounds to disinfect or to excise them, nor is it necessary to amputate members of the body; the antitoxin being able, as soon as injections are begun, to take care of and neutralize all the toxin as fast as it is produced.

The drug treatment consists almost entirely of sedatives in large doses; the heart's action being kept up at the same time with stimulants, introduced by rectum, if necessary, and digitalis and nitroglycerin by hypodermic medication.

The serumtherapy offers very favorable prospects for the cure of tetanus. In experiments made upon animals, it was found that the injections of antitoxin would either save them from infection, or cause a cure after the outbreak of convulsions. The serum must be of a high class and of a definite quality. It has no specific poisoning effect on the organism. Steuer proved that a neutralization of the toxin by the antitoxin takes place in a thoroughly mechanical manner; this new combination being in itself harmless. Antitoxin affects only the toxin in circulation, not that already taken up by the nerve-cells. We cannot act by injections upon the poison already in combination with the protoplasm. The serum must be absolutely sterile. If possible, the first injection must be given inside of the first 24 hours after the outbreak of the symptoms, and must be copious in quantity. It can be given either subcutaneously, intravenous, subdural, or intracerebral. Subcutaneous injection is used principally in the preventive treatment and is of little benefit after tetanus has appeared; it must be used in very large doses. The intravenous is somewhat more favorably looked upon, but must also be used in large quantities, and is not as effective as the remaining two classes of application. The best injection of all is the cerebral injection, which demands, however, a special technic for the carrying out of the operation, as the antitoxin serum must be introduced into the lateral ventricle itself. This can be best done according to the methods of Alexander Fraenkel or Albert Kocher. Dr. Frank Hartley, of New York City, has recently perfected a new method by which he is able definitely and certainly to inject the antitoxin into the lateral ventricles. The subdural, or spinal, method is explained by its name, the antitoxin

being introduced beneath the dura, through a spinal foramen.

The quantity of antitoxin injected by either of these methods depends somewhat upon the severity of the symptoms, bearing in mind that a proper serum is harmless and too much cannot be given. Some authors advise that the intracerebral injection should be assisted by copious subcutaneous and intravenous, as well as subdural injections.

Together with the serum treatment, chloral and the bromides should always be used. This combination-method offers the best hope of favorable result.

Our antiseptic measures against a germ as tenacious of life and as virulent as the tetanus spore is known to be, are not satisfactory and complete. The ordinary disinfection of the hands and the wound location as practised in the hospitals and in private cases will not destroy this bacillus; and until we have some more certain way than that at present in use, we can never be sure, in the presence of this bacteria or its spore, of preventing tetanus. I present, therefore, for your consideration these few suggestions as to the preventive and curative treatment in operative cases where a possible tetanus germ is lurking.

ADHESION OF THE SOFT PALATE TO THE POSTERIOR WALL OF THE PHARYNX.

By AUGUSTUS KOENIG, B.S., M.D.,

of Philadelphia.

THE influence of nasal obstruction upon the general health and the comfort of the individual is a very profound one and one whose dangers should not be overlooked.

When nasal breathing is impossible, it must of necessity be supplanted by mouth breathing, the evils of which are very obvious. Firstly the air which in our cities and workshops is thoroughly dust-laden, is taken directly into the pharynx, trachea and lungs, instead of being first filtered of its foreign particles by the air-passages of the nose. As a result the dust particles set up an irritation of the throat and lungs. Within certain limits, of course, the respiratory mucous membrane is able to rid itself of and to throw off these foreign substances, ciliated epithelium lining the trachea being especially constructed for this purpose. Should this irritation, however, be continued indefinitely a chronic catarrhal inflammation will be the result, and a condition will be present closely allied to colicosis or anthracosis. Secondly, the air entering the pharynx directly is dry and either hot or cold, depending upon the temperature of the surrounding air and the season of the year. In this case the nose is not capable of carrying out its function of equalizing the temperature of the inspired air and of moistening the same. These factors are all very potent in producing, as a predisposing cause, pneumonia, bronchitis, laryngitis, tuberculosis, etc.

Aside from the possible production, secondarily, of these diseases, profound constitutional symptoms will be present, such as anemia and emaciation, which cause lassitude, headache and a general inability to perform both mental and physical work properly. These conditions are inevitably the result when the blood is not properly oxygenated; and proper oxygenation cannot take place in a lung whose mucous membrane is in

a chronic catarrhal state, and where a sclerosis or overgrowth of connective tissue has taken place.

These facts will be illustrated by the following case, in which there was practically a complete nasal obstruction, owing to an adhesion of the soft palate to the posterior wall of the pharynx. Operation in this case was followed, not only by local improvement, but also by a very marked improvement in the general health.

Mr. R. C., in October, 1898, presented himself for examination and treatment. His father died at 62 and his mother at 40 years of age. They both died of diseases which were unknown to the patient. There was probably no tuberculosis or cancer in the family history. The patient is 34 years old, was born in Glasgow, Scotland, and is a machinist by trade. Measles is the only disease of childhood from which he suffered. When 11 years old he caught cold, which resulted in an ulcerated sore throat lasting 8 months. In healing, union took place between the soft palate and the posterior wall of the pharynx, completely closing the posterior nares, and also attended by total loss of hearing. There is absolutely no history of syphilis. The patient went to the Western Infirmary of Glasgow for treatment. Some polypi were removed and his throat operated upon, but apparently with little success, as far as the breathing was concerned. The hearing, however, was greatly improved after the operation. In October, 1898, I found on examination that the anterior nares were fairly clear. There was an adhesion of the palate to posterior wall of the pharynx, extending from the right side to within $\frac{1}{4}$ inch of left side. The communication between the nose and mouth was scarcely enough to admit a retractor. Nasal breathing was almost completely abolished. By a great effort the patient was able to draw a small amount of air through the nose. Owing to the mouth-breathing, the mucous membrane of the pharynx was atrophied, dried, parched, and shining. The patient was very thin and pale from the anæmia. He was easily fatigued, and it was only his strong will power which enabled him to carry on his work successfully.

No general anæsthetic was given for the operation, but the parts were thoroughly cocainized with a 5% solution of cocain. The separation of the soft palate from the wall of the pharynx was begun with a properly curved pair of scissors. After the opening was considerably enlarged the total separation was accomplished by an instrument which I had made, having the general curve of a Gottstein curet, but having a double lateral cutting edge. The cocain had such a contracting influence upon the capillaries that the bleeding was not at all excessive.

After the operation the soft palate was freely movable and the patient was gratified by being able to draw his first good breath. By means of a Belloque's canula a thread was passed through the nose into the mouth. An antiseptic gauze plug was attached to this and the nasopharynx well plugged to prevent hemorrhage. This plug remained in situ for 48 hours, when it was removed and the cavity well cleansed with Dobell's solution and covered with a powder of aristol and tannic acid.

The gauze plug was not used after the first 48 hours, but it was replaced by a hollow silver plug which was specially made to fit the cavity.

Through this silver plug the patient was able to breathe perfectly, and yet the freshly cut surfaces were held apart and thus prevented from reuniting. By means of a spray the patient was able to keep the parts clean. Healing took place in 3 weeks.

Twenty months have elapsed since the operation and there has been no return of the trouble.

Formosa.—News has been received at the Western coast of America of a fresh outbreak of the plague, 7 deaths having occurred in 7 days.

THE TREATMENT OF ERYSIPELAS.

By N. G. KEIRLE, JR., M.D.,

of Baltimore, Md.

Physician in charge, Bay View Hospital.

DURING the last fifteen months we have treated about 30 cases of erysipelas by the following method, and with such uniform success that we no longer fear the disease. In fact, not a single case has failed to yield to treatment in a few days, usually three or four.

The affected area is first enclosed in a painted ring of tincture of iodine. The ring is not to be started at the margin of the reddened area, but from 2 to 3 inches from it, and a sufficient number of coats should be applied to cause a slight desquamation of the upper layers of the skin. At the same time the whole surface enclosed in the ring is to be covered with an ointment of ichthyol, about 1 dram to 1 to 2 ounces of vaselin. This is covered with a piece of gauze and a hot stupe applied and changed about every 4 hours. At the end of 12 hours the ichthyol ointment is washed off and a fresh coat applied, and if the iodine has not had sufficient effect, one or more new coats are applied. Internal treatment may or may not be instituted, as the result is the same in either case. Although both iodine and ichthyol are used in the treatment of erysipelas we have not heard of any cases treated as above. In our cases three or four days of this treatment have not failed to stop the trouble, the inflammation not crossing the painted line of iodine except in one case, in which another ring painted further out, and the same treatment as at first, effectually stopped the spread of the trouble. We make no claim to originality, but cannot remember having seen the above used, and the success is so uniform that we offer it as a suggestion to those who have had trouble in checking this, at times, troublesome disease.

Wound of the Left Vertebral Artery.—Bouchaud reports (*Revue de Med.*, Nov. 10, 1900) the case of a man, aged 40, who, in Nov., 1896, was stabbed during a quarrel in the upper portion of the left side of the neck. Two days after the accident he had partial loss of consciousness, which lasted 8 days. In the beginning, all 4 limbs were paralyzed as were also the muscles of the trunk and of the neck. The paralysis was flaccid, and was unaccompanied by rigidity or convulsions. For 15 days the patient had retention of urine with incontinence, and pronounced respiratory difficulty. Sensation was almost completely abolished, except in the face; but, nevertheless, he had for nearly 4 months sharp lancinating pains in the shoulder, back, and feet. There was no vomiting, no difficulty in swallowing, and there were no bedsores. The symptoms disappeared gradually, and at the end of 7 months the patient began to walk. In April, 1898, examination showed a scar just behind the mastoid process. The patient could walk, although his legs were weak, but the patellar reflexes were normal. The hands were weaker than the legs, and the dynamometer showed greater weakness in the left than in the right hand. Sometimes there were involuntary contractions of the fingers and frequent twitches in different parts of the body. Speech was somewhat embarrassed. There was a marked change in the general sensation, except in the face, but sensations of heat and cold were readily perceived, and sensation produced by the prick of a pin was exaggerated. While he could walk, the patient could not tell the character of the material on which he stepped. The respiratory, circulatory, and digestive functions presented nothing abnormal. In October, 1898, the symptoms were less marked. The author believes that the vertebral artery was wounded, and that the blood was effused between the dura mater of the cord and the vertebrae; the resulting compression of the spinal cord producing the symptoms. The Method of Transmission of Yellow-fever.—

In 1881, Charles Finlay, of Havana, first conceived the idea that the yellow fever organism was conveyed from patients to nonimmunes by mosquitoes. He tells us in his address before the Pan-American Medical Congress at Havana that this idea first occurred to him upon studying a report published by the Navy Department in 1880 "On the Yellow Fever on the United States Steamship *Plymouth*." In a footnote in this report is contained the following opinion of Dr. Bemiss: "The poison of yellow fever is reproduced chiefly, if not wholly, in the body of the patient, but undergoes some change after it escapes from the body which increases its toxic quality." This statement gives no clue to the mosquito theory of transmission, but it is interesting in that it suggested the line of thought which led to Finlay's theory. There had been previous observations on the increase in the number of mosquitoes during yellow fever epidemics, but to Finlay belongs full credit for the development and exposition of this view. For many years he was met by strong opposition, but continued his experimental studies. In June, 1900, the Surgeon-General of the United States army appointed a board for the purpose of pursuing scientific investigations with reference to the acute infectious diseases prevalent in the Island of Cuba, which was composed of Dr. Walter Reed, Dr. James Carroll, Dr. A. Agramonte and Dr. Jesse W. Lazear. According to its preliminary report (PHILADELPHIA MEDICAL JOURNAL, October 27, 1900) the Commission failed to isolate the *Bacillus icteroides* either from the blood during life, or from the blood and organs of cadavers. They turned their attention to Finlay's theory, being impressed by the brilliant work of Ross and the Italian observers in connection with the mosquito-malaria theory. They felt justified in concluding that Finlay's view was the correct one and they formulated this opinion by stating that "the mosquito serves as the intermediate host for the parasite of yellow fever, and it is highly probable that the disease is only propagated through the bite of this insect." Many yellow fever experts did not believe that the Commission was fully justified in its conclusions from the facts at hand. There was a feeling that some other means of infection than the mosquito might have been responsible for attacks observed. However, the Commission continued its work with unremitting zeal, and its Additional Note

upon "The Etiology of Yellow Fever," read before the Pan-American Medical Congress in Havana and published in the *Journal of the American Medical Association* (February 16, 1901), confirms beyond peradventure the correctness of the original views. These conclusions are well worthy of repetition. It is now determined that the *Culex fasciatus* serves as the intermediate host for the parasite of yellow fever, and it is also determined that this variety is identical with the so called *Culex tiniads* as described by Giles. Theobolt (according to Howard) separates *Culex tiniads* from the genus *Culex* and places it in a new genus, *Stegamina*. It may now be accepted that malaria has a genus of its own, *Anopheles*, and yellow fever, the genus *Stegamina*. Yellow fever, they have shown, is transmitted to the nonimmune individual by means of the bite of a mosquito that has previously fed on the blood of those sick with the disease, and it appears necessary that an interval of about twelve days must elapse before the mosquito is capable of conveying the infection. The bite of a mosquito at an earlier period after contamination does not appear to confer any immunity against a subsequent attack. The Commission have also succeeded in producing yellow fever experimentally by the subcutaneous injection of blood taken from the patient during the first and second days of the disease, and it has also determined that an attack of yellow fever produced by the bite of the mosquito confers immunity against the subsequent injection of the blood of an individual suffering from the non-experimental form of this disease. They have further proven that the period of incubation, in 13 cases of experimental yellow fever, has varied from 41 hours to 5 days and 17 hours. Most important is their conclusion that yellow fever is not conveyed by fomites and that it is consequently unnecessary to disinfect articles of clothing, bedding or merchandise supposedly contaminated by contact with those sick with the disease. They observe that a house may be said to be infected with yellow fever only when there are present within its walls mosquitoes capable of conveying the parasite of this disease. In consequence the spread of the fever must be controlled by measures directed to the destruction of mosquitoes and the protection of the patients against the bites of these insects. The Commission seems to have established definitely the mode of propagation of yellow fever, but they have shown that the specific cause of the disease remains to be

discovered, thus summarily disposing of Sanarelli's claims.

Dr. John Guit  ras, a well-known authority upon yellow fever, was one of those who at first opposed the mosquito theory, and especially the conclusions which the Commission set forth in their preliminary report. In a recent contribution to *Revista de Medicina Tropical* of Havana, however, he accepts unreservedly the later conclusions of the more elaborate studies of the Commission. It will be seen that scientific research has accomplished more of practical value from the study of the theory of infection than from the bacteriological causes of disease.

This subject opens a vast field for preventive medicine, and it would seem reasonable to assume that enteric fever may soon be included in the category of those infections whose transmission is brought about, and in consequence, the epidemic character maintained in part by flies, gnats or other insects. It is interesting to conjecture whether in the case of enteric fever the offending insect will be found to be of one variety as in yellow fever and malaria.

The Literary Morals of the Antivivisectionists.—

Dr. Keen's reply to the Antivivisectionists (published in this number of the JOURNAL) is more than a criticism; it is in itself a fine example of human vivisection. It is not quite so bad as cruelty to animals, because animals at least are always ingenuous and innocent, whereas these particular antivivisectionists are, as Dr. Keen shows, just the reverse. The scarification administered to Mr. James M. Brown, is fortunately done by a surgeon so eminent as Dr. Keen, so that Mr. Brown will have no occasion to complain in the future that he was not scarified by skilled hands. When the President of the American Humane Association again takes up the cause of suffering humanity he will have himself to attend to first, and when he wishes to find an example of a surgeon who can dissect a man alive, his thoughts will doubtless revert instinctively to Dr. Keen.

As for the controversy itself (if that can be called a controversy which is rather a case of literary detective work) we cannot do better than refer our readers to the letters themselves. Dr. Keen shows, with a precision and scorn worthy of Junius, that the antivivisectionists in their pamphlet had descended to the methods of literary dissimulation. In a perverted cause, which they proclaim to be one of truth and humanity; they have employed the weapons of misrepresentation and false witness. With the merits of vivisection, as an absolutely essential aid to scientific medicine, we are not at present concerned—neither are we concerned with the merits of the antivivisectionists, for those persons among them who are responsible for their pamphlets, have apparently no very conspicuous merits to speak of. We are quite willing to accord to public opinion and to the law-making powers the right to demand full knowledge

on this whole subject of vivisection. We can quite readily concede that as a method of science it may be subject to occasional abuse, and should be properly supervised by law; we can even understand that the sympathies of some high-minded persons are not unnaturally stirred by the exaggerated tales from the laboratories; but, with all this, we cannot sufficiently condemn the ignorance, willfulness and perversity of persons who, like Mr. Brown, seek to cast opprobrium upon scientific medicine for its splendid achievements in modern bacteriology and pathology, and who in their so-called logical methods seek constantly, in the language of Socrates, to make the worse appear the better reason.

A Doctor as Major-General.—Among the names of the 16 army officers, recently sent to the Senate by the President for promotion in the U. S. regular army, was that of a doctor of medicine. This is noteworthy because the appointment is in the line, and not in the medical staff. It is unprecedented, so far as we can recall, either in this country or in any other; in fact, in any other country than this such a promotion would, we suppose, be practically impossible. The officer thus distinguished is Dr. Leonard Wood, the well-known military Governor of Cuba. Doctor, or General, Wood is a graduate in medicine of the Harvard Medical School. His distinguished career in Cuba is too familiar to all readers to need to be recalled here. It is sufficient to say that this career has been in both the military and civil service, and not in a medical capacity. We understand, however, that General Wood held the regular army rank of assistant surgeon, and that therefore his promotion by such a great leap has called forth criticism in army circles, in which it is regarded as practically an appointment from civil life to high rank in the regular army. We are not specially concerned here about these caste distinctions, and we see no reason why a medical man should not be thus advanced in a service in which lawyers and business men are sometimes honored with high military rank. General Wood has earned his promotion as clearly as any of the other appointees. It is not unusual for physicians in this country to gain high political positions. They have been members of Congress and Governors of States, and perhaps it is reserved yet for one of them some time to be President. It is highly desirable, in fact, that the profession should be better represented in the civil service of the country, especially in the law-making branches.

The Medical Examination of School Children.—In his very interesting annual report to the Board of Public Education of this city, the president, Samuel B. Huey, Esq., devotes some space to the subject of the medical inspection of school children. He gives some figures which make interesting reading. In the report of the visiting physicians it is shown that from January 1 to

October 31, 1900, there were 3,446 cases of *contagious* diseases detected in the schools of this city. Among these diseases were diphtheria, measles, mumps, whooping-cough, syphilis, impetigo, ringworm, epidemic conjunctivitis, and lice. This is a goodly showing, and would seem to vindicate the wisdom of those who have advocated and succeeded at last in establishing this system of inspection. 212 cases of lice, 116 cases of impetigo, and 753 cases of ringworm, turned loose in our public schools, help to make splendid breeding grounds out of these nurseries of learning for some rather unpleasant affections. Surely no advocacy is needed after this for a thorough system of medical inspection and control. Of noncontagious diseases 2,430 cases were reported—1000 fewer than the contagious cases. This is also significant, for it shows that the more serious affections are in excess of the less troublesome ones. In the JOURNAL for last week we published an interesting paper on this subject by Dr. Greene, Inspector of Public Schools in Boston, in which he describes in detail the admirable system adopted in that city. Boston, we believe, was the first city to adopt a system of inspection; and, it is to be noted, that city is paying its medical inspectors for their valuable services while Philadelphia is still meditating over it. The salaries in Boston, to be sure, are not high, but they are something to the young men who are devoting their time and expert knowledge to the public service. Too much public medical work is already done for nothing by men who can ill afford it, and we do not quite agree with Mr. Huey that the subject is "a many-sided one." We think it is only a one-sided one. If, as Mr. Huey quotes in his report, the work of the medical inspectors during this last year has averted epidemics, this work is worth paying for. If it is desirable that our public schools should not become hotbeds for loathsome diseases and foci from which these diseases can be spread broadcast, then it is also desirable that the educated physicians who give their skilled services should be paid for keeping the schools free from contagion. The janitors are paid for cleaning out; why are not the young doctors? But Mr. Huey promises that the subject shall receive the "thoughtful consideration of the Board." It is but just to the Board to say that the fault is not with it, but with Councils.

Asthenic Bulbar Palsy.—This affection, which is a good example of a bad disease with a worse name, has recently been interesting the neurologists, and has been described, with reports of cases, by Dr. Charles W. Burr and Dr. D. J. McCarthy, in the January number of the *American Journal of the Medical Sciences*. We are inclined to criticise the name—a name for which Dr. Burr and Dr. McCarthy are not responsible—because, first, most if not all paralytic affections are in their very nature *asthenic*, and therefore this term as applied to this disease is not sufficiently distinctive;

and, second, because this particular disease, while often presenting bulbar symptoms, is by no means confined to the medulla oblongata, and is sometimes apparently not even distinguished by marked bulbar involvement. The name *myasthenia gravis* is better in some respects and worse in others, for while the disease is sufficiently grave it is probably not located in the muscles.

Asthenic bulbar palsy was first described by Wilks in 1877, and about 60 cases have since been put on record. It is, in brief, a disease marked by progressive weakness, involving often the extremities, and accompanied, as a rule, with such bulbar symptoms as tremor and weakness of the lips and tongue, and impaired deglutition; also, in some cases, with slight involvement of the orbital muscles. The reflexes may be preserved or even exaggerated. The disease seems to be confined largely to the motor neurons, but sensation may in some instances be somewhat impaired. At autopsy but little is discovered to account for the symptoms, and in this respect the disease has been something of a mystery. Dr. Burr and Dr. McCarthy in one of their cases found no gross lesions, but under the microscope they observed chromatolytic changes, with swelling and displacement of the nuclei, in the nerve cells in the medulla oblongata. In the tenth nerve atrophy of some fibers was observed, and very slight changes in the twelfth. The muscular fibers were normal. It is thus seen that astonishingly little was observed to account for a disease which was evidently capable of making extensive ravages of a most minute kind in the nervous system, and yet of leaving few traces of its destructive course. In discussing the disease the authors feel compelled to fall back upon general physiological and pathological laws, and to draw inferences from analogous affections. They conclude that the disease is probably located in the motor neurons, and that it is due to the activity of some toxin. It is not confined to the motor neurons arising in the bulb.

We think these conclusions are just, and that asthenic bulbar palsy may be relegated to that class of insidious disabling affections which are to be regarded as in a general way due to some intoxicants. Landry's paralysis, while clinically different, is still in this list, and Bell's mania, although a psychosis, is probably another instance. It may be recalled that some of the most violent poisons, such as those of tetanus and hydrophobia, as well as such drugs as strychnia and morphia, can do their deadly work and leave scarcely a trace behind. With improved microscopic technic we have come far enough to recognize some minute changes in cytoplasm which show these results in dead, not living, matter, but even the most enthusiastic among us will hardly claim that we can read the secrets of many diseases in dead cytoplasm.

Anesthesia from Subarachnoid Injection of Cocaine.—In 1891, when Quincke first proposed lumbar

puncture of the subarachnoid space, he believed that the proceeding would be useful from a therapeutic standpoint. On the contrary, the operation has developed, in the hands of the physicians, into a diagnostic measure of great value. The surgeons, however, have utilized the method for the purpose of injecting cocain into the subarachnoid space in order to produce anesthesia. Tuffier is one of the foremost advocates of this method of producing anesthesia. His first paper appeared in 1899, and has been followed at various intervals by others detailing results of his work. Recently (*Semaine Médicale*, December 12, 1900) he has published the results of 252 operations which he had performed under medullary anesthesia. These operations ranged in severity from curettement of abscesses to gastroenterostomies, 6; nephrectomies, 2; and other intraperitoneal operations, in all, 142. Among the symptoms noted during the period of anesthesia are a slight general malaise and nausea, or vomiting; the latter symptom in 20% of the patients operated upon; the pulse is accelerated and a little soft. After the anesthesia there is a sensation of thirst that lasts 2 or 3 hours, the temperature is frequently elevated, and there is, in the majority of the patients, considerable headache, the pathogenesis of which is unknown. Tuffier considers this method of producing general anesthesia to be perfectly safe, and says that he has never seen the symptoms assume such an intensity that he feared for the life of his patient. So far as extraperitoneal operations are concerned, he thinks that medullary anesthesia will stand favorably in comparison with general anesthesia. He advises only those who are thoroughly familiar with intraperitoneal surgery to employ the method for abdominal operations, on account of the anxiety that would be caused by the nausea and vomiting. There has been but one death after operation done under anesthesia thus produced; the patient succumbed during a journey undertaken after his convalescence. At autopsy, this patient was found to have had serious cardiac lesions with congestion and edema of the lung.

Some surgeons in this country have adopted this method of producing anesthesia when the operation is to be done below the diaphragm. In the *PHILADELPHIA MEDICAL JOURNAL* for November 3, 1900, Fowler gives the results of 41 successful applications of the method; Goldan reports 18 successful cases, and 2 failures; and Keen reports one case that terminated fatally 18 days after the operation, from exhaustion and urinary sepsis. In this case eucain was used instead of cocain. Lee reports 7 cases; Rodman 2; LaPlace 2; and Marx reports 42 cases in which the method was used for the performance of obstetrical operations or to relieve the pain of normal labor. One great objection to the method is the mental anguish that must be produced by the manipulations and the surroundings of the operation. In order to prevent this mental shock,

some operators have blindfolded the patients and stuffed their ears with cotton-wool.

It seems to us that the surgeons are very fortunate not to have had a greater number of unfavorable results following the employment of this method. Of course, a man who undertakes an operation under this form of anesthesia will be extraordinarily careful at first, but as he becomes more used to the method, may he not become less particular, and may he not have sepsis as a result? Surely, the introduction of $\frac{1}{2}$ grain of cocain into such an extensive lymphatic space as the subarachnoid space of the cord must be attended with some risk, and what is to prevent dangerous cocain poisoning? Indeed may not the headache, the pathogenesis of which Tuffier is unable to account for, be due to the absorption of the drug? Still, the results so far reported seem to favor the method in some fields of surgery. In a former comment in this *JOURNAL* we called attention to possible psychic or neurotic manifestations, as results of mental shock. In the present number we publish an interesting report of a double amputation of the feet under cocain anesthesia.

The Medical Aspects of the Siege of Peking.—

In the *China Medical Missionary Journal* for January, 1901, there is an interesting account by Dr. Lillie E. V. Saville of hospital experiences during this celebrated siege. The number of medical men and women who were present during the siege was quite remarkable; altogether there were of all nationalities 20 men and women with medical and surgical degrees. On June 21 the International Hospital was organized in the British Legation. Mr. Cordes, who was wounded at the time the German minister was killed, and a Russian student with a penetrating wound of the shoulder joint, were the first patients. Dr. Poole of the British, and Dr. Velde of the German, Legation were on the staff, and Miss Lambert was the nurse. The women doctors were asked to act as nurses, a position which was gladly accepted by them. The impromptu hospital was not so badly off for surgical dressings, as Dr. Velde had a large supply of the kind used in the German army. He had also a sterilizer. Instruments were always sterilized before operations. To most of the medical attendants the experience with shot and shell wounds was new, and they had much to learn. The hospital gradually grew until it included an operating room, five wards, and a convalescent ward for officers and civilians (this last in Lady Macdonald's house), and another for the marines elsewhere. Three American ladies superintended the kitchen, and their work was beyond all praise.

Dr. Saville says that the hospital had first claim to the commissariat stores, and that nowhere else were there such fragrant pony soup and such really eatable mule stew; and these delicacies were so appreciated

that she thought the officers and men considered it worth while to be slightly wounded in order to get a few days of such feeding. Owing to the difficulties caused by diverse languages, the patients were warded according to nationality. Italians and French were put together with a French Sister in charge; Russians were in another room where they were most tenderly cared for by Madame de Giers herself—the Russian Minister's wife. With the Russians were put the Germans, while one room was always full of the bright little Japs. English and Americans naturally went together. There was only one room, however, for officers and civilians, and here were nursed British, Americans, Germans, French, Italians, Austrians, Dutch, Australians, and Russians—a polyglot assemblage. It was wonderful how the stores and supplies were kept up. They represented much self-denial on the part of others and exhibited many expedients. The pillows were made from the packing straw of wine bottles; shirts were made of the best damask linen or of bright yellow cotton. There were few bedsteads; mattresses being placed on the floor, but every wounded man had a mattress with sheets and pillows.

Bullets were rarely hunted for at the first dressing, but, considering the circumstances, a fairly good asepsis was maintained. Flies were the chief plague of the sick. The fighting being done mostly behind barricades, the proportion of head injuries was large. Some cases of recovery are mentioned that are almost marvelous in view of the surroundings. Dr. Saville gives a description of some of these wounds, and says that operations were undertaken for their relief not unsuccessfully amid these distressing circumstances. Two cases of tetanus occurred. One of these happened to a member of the Japanese Legation, his wound having become contaminated by the flies which had laid their eggs under the dressings. These cases of tetanus were fatal. An exciting episode was caused by a case of strychnin-poisoning. A Russian had taken some of the drug from a bottle in mistake for sodium bicarbonate. His life was saved, apparently by chloroform inhalation and induction of free vomiting.

Toward the close of the siege diarrhea and dysentery were prevalent. There were two deaths from the latter disease among the Russians, who were known to be exceedingly careless about their drinking water. There were also three cases of typhoid fever, one proving fatal after the end of the siege. During the siege there was no death in the hospital of any patient who survived his injury 24 hours, excepting in the two cases of tetanus; but two patients died afterwards. Dr. Saville says that the harmony of action among all persons who attended upon the sick and wounded was a striking feature of the siege of Peking. Differences of creed and nationality and of professional status were laid aside, and all worked together with much happiness

and devotion. The report of this noble work deserves to be spread widely abroad.

Forest-camps for Cases of Tuberculosis.—We wish to endorse most heartily the proposition of State Forestry Commissioner, Dr. J. T. Rothrock, to establish camps on various suitably situated forest-reservations in Pennsylvania where tents will be erected for the free use under proper regulations of tuberculous citizens who desire to avail themselves of the benefits of open-air treatment, but are unable to secure other change of climate. Pure air and sunshine constitute a potent factor in the prophylaxis and treatment of tuberculosis, and the plan proposed is entirely in the line of modern practice, from the medical as well as from the philanthropic point of view.

Acute Ulceromembranous Angina in Children Due to the Fusiform Bacillus and Spirillum of Vincent.—Aurel Athenasius (*Gaz. Heb. de Med. et de Chirurg.*, December 30, 1900; 47me Année, No. 104; Paris Thesis, 1899-1900, No. 550) has made a complete study of ulceromembranous angina in children and shows that the fusiform bacillus and the spirillum of Vincent are the specific agents of the disease for the following reasons: 1. The considerable quantity in pure culture of these microorganisms in the false membrane at the beginning of the angina, even before the appearance of ulceration. 2. The almost inevitable association of the bacillus and the spirillum in the false membrane. 3. The absence, or at most the presence of very few microorganisms of the mouth. These organisms have lost themselves in the matting formed by the interlacing of the spirilli and bacilli. 4. The diminution of the number of bacilli and spirilli of which the false membrane is composed as the ulceration proceeds towards cicatrization. 5. The concomitant disappearance of all the signs that give this variety of angina its special aspect. 6. The coincident appearance in the false membrane and in the neighborhood of the tonsils, of a large number of the normal buccal microorganisms that have been supplanted during the disease by bacilli and spirilli. 7. The rapid repair of the lesions at the same time that the specific agents diminish in number. The reappearance of large numbers of specific microorganisms and the extension of the lesions whenever some unfavorable feature interrupts the regular progress of the disease. In order that these microorganisms may become virulent it is necessary that favorable conditions of soil and bacterial association be present. From the clinical point of view the affection may be divided into two periods: First, the period of false membrane formation; and, second, the period of ulceration. Each of these stages of the disease has its special clinical manifestations and the second stage always succeeds the first. The author has never seen cure follow the first period; in all cases ulceration has followed the development of the false membrane. In the stage of ulceration the diagnosis is only to be made from primary or tertiary syphilitic lesions by bacteriological examination of the membrane. Bacteriological examination will also differentiate the disease from diphtheria. The course of the affection is acute and lasts about 15 days. The result is always favorable, and the treatment consists of washing the nose, pharynx, and mouth with a weak solution of permanganate of potassium. [J.M.S.]

Reviews.

Panama and the Sierras. A Doctor's Wander

Days. By G. FRANK LYDSTON, M.D. 12mo, pp. 283. Illustrated from the Author's Original Photographs. Chicago: The Riverton Press, 132 Market Street. 1900. Price, \$1.75. Prepaid.

This interesting little book is not too medical for the laity and not medical enough to tire the physician who desires a few moments of recreation. It comprises a series of interesting anecdotes and reminiscences told in a charming manner. The illustrations are produced from original photographs taken by the author and are quite impressive. The Sierras and the Isthmus of Panama are so ably described that one can almost feel the tropical zephyrs and sunshine. There is an instinctive desire to finish the book after it has been begun, and to describe its contents would be detracting from the interest of those who intend to read it. Concise, witty and instructive, "A Doctor's Wander Days" is a pleasant divertissement after a doctor's busy day. [M.E.D.]

Obstetric and Gynecologic Nursing. By E. P. DAVIS, A.M., M.D. Professor of Obstetrics in Jefferson Medical College and Philadelphia Polyclinic. 12mo, volume of 402 pages. Illustrated. Philadelphia and London: W. B. Saunders & Co., 1901. Price, \$1.75 net.

As is stated in the preface, this volume is designed to furnish instruction as to the various duties of the obstetric and gynecologic nurse, and while dedicated to the training schools of the Jefferson and Philadelphia Hospitals, it can not fail to be of the utmost value to the well trained nurse wherever she may be. It is well-known that too many nurses receive their diplomas with almost no knowledge of obstetric requirements and often with absolutely no obstetric training. The theoretical portion of this defect can be largely remedied by a perusal of Dr. Davis's most excellent book, to the preparation of which he has brought the experience of many years of a large and varied practice. Not only are the duties of a nurse in attendance upon a woman in labor described, but chapters are also given to the nurse's duties in the latter months of pregnancy and when called upon to assist in the various obstetrical and gynecological operations. Numerous illustrations still further elucidate an instructive text, and a system of black captions renders reference easy. The book must fill a long-felt want to both physician and nurse. [W.A.N.D.]

Medico-Surgical Aspects of the Spanish-American War. By LIEUTENANT-COLONEL NICHOLAS SENN, M.D. 8vo, pp. 379. Chicago, 1900.

In this book are collected the letters contributed to the *Journal of the American Medical Association* by Dr. Senn while he was a medical officer in the service of the United States.

Although a considerable part of the book relates to matters of nonprofessional interest, many of its pages deal with subjects of the highest medical importance. Even when the author treats of subjects outside of the domain of medicine he brings to bear upon the discussion his well-known professional acumen. Medical readers will therefore constantly find important professional observations recorded. For example, Dr. Senn speaks of the great number of hernias found in men who had gone through the campaign. The evidence seemed to show that this condition was produced, not by hard marching or violent exertions, but by "the relaxation of tissue, caused by disease and its effects, aided undoubtedly by the prevalence of intestinal affections which must have often resulted in increased abnormal intraabdominal tension."

The frequency of varicocele in recruits was greater than would have been expected. Very few of the cases, however, were sufficiently important to call for active surgical treatment. The infrequency of appendicitis in the many thousand soldiers directly or indirectly under the observation of Dr. Senn is remarkable. He says that at Camp Wikoff not

one case came under his observation which would have justified operation.

A partial list of the titles of the letters will give an idea of the scope of the volume: "Typhoid Fever in the Porto Rican Campaign," "Recent Experiences in Military Surgery after the Battle of Santiago," "The Surgery of Camp Wikoff," "Nurses and Nursing in War," "Physical Characteristics of Ten Thousand Men," "A Compact Operating-Case for Military Service." These titles are sufficient evidence of the value of the book to both military and civil practitioners of surgery.

Dr. Senn's remarks on the qualifications and duties of the military surgeon will appeal to all practical men. He says "The surgeon who understands the principles and practice of good cooking is of more service to the troops than the one who can repeat, word for word, the contents of the most exhaustive treatise on *materia medica* and therapeutics. The medical officer with a full knowledge of hygiene and sanitation and endowed with the faculty of making a rational, practical use of it is preferable to the most expert clinician." [J.B.R.]

The History of Ancient Gynecology. By W. J.

STEWART MCKAY, M.B., M.CH, B.Sc., Senior Surgeon to the Lewisham Hospital for Women and Children, Sydney; Late Surgeon to the Benevolent Asylum Maternity Hospital, Sydney; Fellow of the British Gynecological Society, and of the Obstetrical Society, of London. Pp. 302. New York: William Wood & Co., 1901.

The writer of this work must certainly be credited with enormous patience and industry, all the more remarkable because of the difficulty in obtaining access to the ancient authorities which a residence in Australia must entail. In writing the history of ancient gynecology as it has never been attempted before, he has set down in the form of extracts or summary all of importance that may be found relating to this branch of medicine in the extant writings of Egyptian, Hindu, Greek or Roman authors. He has utilized translations of Egyptian and Arabic authorities, but has mostly consulted originals. A brief sketch is given of the life and works of the more celebrated authors, such as Galen, Hippocrates or Soranus, after which are collected all the statements of each concerning the diseases of women. The writer is able to say that he believes he has neglected no work among ancient classical authors of any importance which contains any passages on gynecology.

While finding little in the Jewish Talmud worth incorporating in his book he notes as a point of interest gathered from the commentaries written in the first five centuries of our era that the Rabbins made many vaginal examinations. They discovered that hysterectomy was possible in animals and had undertaken cesarean section on the living woman. Gonorrhea is also frequently mentioned in their writings. The oldest work on medicine is a papyrus, obtained in Egypt by Ebers in 1872, dating from the sixteenth century before the Christian era. Though the part of the work specially devoted to gynecology has not been preserved, some facts relating to the subject are to be found in the portions extant. There are here references to uterine prolapse, to the use of the medicated tampon, the suppository, the enema, etc. Specialism in medicine is not a modern development, for Herodotus, the Greek historian, says of the to him ancient Egyptians: "Some physicians are for the eyes, others for the head, others for the teeth, others for parts about the belly, and others for internal disorders."

How many centuries has it taken before mankind learned through aseptic methods to read literally these words of an old Greek physician: "The napkins must be kept clean, be of soft texture, as also the linen used for the eyes, and the sponges for the wounds; for these things are of great importance for the healing."

Hippocrates (460 B. C.) describes a method of applying the Trendelenburg position for the treatment of prolapsus uteri which is simple and effective. Cushions were placed on a ladder, the patient tied on by ankles, knees and thighs. One end of the ladder was then raised against the gable end of a house!

In the literature of Hindu medicine, which may antedate Christianity by a thousand years, are references to the trocar for tapping dropsy and presumably ovarian cysts; to the suprapubic operation for stone in women; to the catheter; to nutrient enemata, and numerous instruments, including the three-cornered surgical needle.

The catgut ligature for vessels and the knee-chest position seem to have a very ancient origin. The reader of this most interesting book will surely be inclined to agree with Solomon who wrote that there was nothing new under the sun. Since it is also true, as the same writer has said, that of making many books there is no end, it is helpful for the student of our art to have access to such a collection of data as that here under discussion. Endless research is thus avoided. Many subjects of interest are summarized in closing chapters, but the absence of an index greatly detracts from its convenience for reference. Every practitioner of the gynecology of today may find profitable food for thought in its perusal. Every gynecological writer should have it. [G.E.S.]

A Textbook on Practical Obstetrics. By EGBERT H. GRANDIN, M.D., Gynecologist to the Columbus Hospital; Consulting Gynecologist to the French Hospital; Late Consulting Obstetric and Obstetric Surgeon of the New York Maternity Hospital; Late Obstetrician of the New York Infant Asylum; Fellow of the American Gynecological Society, of the New York Academy of Medicine, of the New York Obstetrical Society, etc., etc., etc. With the collaboration of GEORGE W. JARMAN, M.D., Gynecologist to the Cancer Hospital; Instructor in Gynecology in the Medical Department of the Columbia University; Late Obstetric Surgeon of the New York Maternity Hospital; Fellow of the American Gynecological Society, of the New York Academy of Medicine, of the New York Obstetrical Society, etc. Third edition, revised and enlarged. Illustrated with 52 full-page photographic plates and 105 illustrations in the text, 6½ x 9¼ inches. Pages xiv-511. Philadelphia: F. A. Davis Company, publishers, 1914-16 Cherry Street. Price, extra cloth, \$4.00, net; sheep, \$4.75, net.

The authors of this well known and well received book have in the present edition maintained the high standard of their previous work. A chapter dealing with the anatomy of the female organs of generation has been added, as well as a section upon elementary embryology. The illustrations are profuse and are largely taken from photographs of the living subjects, although there still remain some of the original plates of manikin-practice. We regret that, some important subjects are disposed of in rather a summary manner not altogether in accord with the status of a textbook. This is eminently true of affections of the fetus and fetal membranes, no mention whatever being made, for example, of malignant deciduoma, which has of recent years assumed an unusual importance in obstetric and gynecologic surgery. The recent pathologic developments also in the same department do not receive sufficient attention, but from a clinical and surgical standpoint the book is well worth a careful perusal. The text is clear and the mechanical work excellent. [W.A.N.D.]

A System of Practical Therapeutics. Edited by HOBART EMORY HARE, M.D. Second edition, revised and enlarged. Vol. I, with illustrations. Philadelphia: Lea Brothers & Co. Price, \$5.00.

This volume is the first of a practically new system of Therapeutics based on Hare's well-known system which was published ten years ago. It is not a mere reprint, or even a second edition in the ordinary sense, but in many respects is a new work. Nearly one-half of the articles are entirely new and the rest of the material has undergone a complete revision. The scope of the work has been enlarged so as to meet the wants of the practitioner in the entire field of medical and surgical therapeutics. Among the subjects which are presented in an entirely new form are Diabetes

Mellitus, Rheumatism, Spasmodic Croup, Scarlet fever, Measles, Rôtheln and Varicella, Typhoid Fever, Croupous and Catarrhal Pneumonia, Dengue, Influenza, Acute Rheumatism and Tonsillitis, Mumps and Diseases of the Mouth, Diseases of the Liver and Gallbladder, Tuberculosis, Rickets, Scurvy, the Diseases of Pregnancy, Parturition and the Puerperium, Fractures and Dislocation, Antisepsis and Asepsis, Anesthetics, Minor Surgery and Bandaging, Disinfection, Mineral Springs, Swedish Movements and Massage.

In the wealth of material contained in this first volume we are impressed with the value of some chapters especially, and we should like to review them in detail if it were possible. Dr. Edward Martin, for instance, has written on the present treatment of syphilis, and has brought the subject thoroughly up to date and presented it in the most practical and interesting way. He believes that mercury should form the basis of treatment in all periods of syphilis, and that this drug is most efficacious when administered by inunction. As to the hypodermic method, Dr. Martin says that there seems to be no reason for believing that it is likely to be adopted as regular treatment in preference to all others. The special indication for this method is found in those cases in which the seat and rapid advance of the syphilitic lesion are such that the patient's life is directly threatened or he is in danger of becoming seriously crippled. This method is, therefore, in our judgment, especially indicated in syphilis of the nerve centers and probably also of the eye. It is contraindicated when the kidneys are diseased or when the patient is suffering from diabetes or marked visceral lesions, anemia, or systemic dyscrasia.

Dr. John K. Mitchell has written a very full and elaborate article on the Rest Cure. In this he embodies the methods of practice which have been used especially at the Orthopedic Hospital in this city under the supervision of Dr. S. Weir Mitchell.

Dr. Simon Baruch has written the chapter on hydrotherapy. The author's well-known predilection for this system of treatment prepares us to expect the very complete exposition of it which he has given in this chapter. He fails to do justice, however, to the work of Dr. James C. Wilson, of Philadelphia, and a few others, in familiarizing the use of the Brand bath in the treatment of enteric fever. The treatment of diabetes mellitus is described by Dr. James Tyson, of Philadelphia, in the complete manner to be expected of such an authority. The article on the treatment of tuberculosis, by Dr. Flick, is, in our judgment, one of the most valuable and complete in the book. It is a review of the subject which practically leaves nothing out of count, and is based on the most recent and scientific knowledge of tuberculosis as an infectious disease.

Professor Remington has given a most instructive paper on prescription writing and the combining of drugs. This ought to be useful to every physician, if every physician will take the time to read it. It is well worth reading, and some parts of it are not a little diverting, especially the section devoted to faults in prescription writing, with fac-similar illustrations. The whole paper is an admirable account of what may almost be called one of the lost arts.

Another important paper is on disinfection, by Dr. W. M. L. Coplin. The author starts with a statement of the theory of disinfection, and then describes all the processes according to the most improved methods. It is a paper of great practical utility.

Time and space will not permit us to mention in detail all the other papers in this volume. Professor Wood's introductory chapter on therapeutic methods is written with the author's usual acumen and in his well-known style. Dr. James Stewart has contributed a very full paper on rheumatism and gout. Among other papers worthy of special note is the one on mineral waters by Dr. James K. Crook, and the one on diseases of the blood by Dr. Ralph Stockman. If the succeeding volumes of this work are brought up to the standard attained in this first volume, they will constitute a work that will be a most valuable addition to the library of every physician who subscribes for it. [J.H.L.]

The Medical Press and Circular states Sir Thornley Stoker is mentioned as a probable candidate for the vacancy on the Council of the Royal College of Surgeons in Ireland, created by the death of Dr. Jacob.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

Professor W. W. Keen has asked for a leave of absence at the Jefferson Medical College in order to take a long trip around the world. He will start next June, after the meeting of the American Medical Association, and will return in September, 1902, to resume his teaching and practice.

The Mutual Aid Association of the Philadelphia County Medical Society has just received \$3,110.55, which is a part of the legacy under the will of the late Dr. Albert Ericke. This, it is understood, is the Association's share of the amount awarded by the Orphans' Court at the first distribution made by the executor.

Dr. John D. Ross, of Williamsburg, Blair Co., Pa., is the oldest medical practitioner in the State. Dr. Ross graduated from the Medical Department of the University of Pennsylvania in 1832. He is now in his ninety-fifth year and in full possession of his mental faculties. Dr. Ross was president of the Pennsylvania State Medical Association in 1863.

Extracted Wrong Tooth.—Suit for \$5,000 was brought against a Philadelphia dentist for the extraction of a wrong tooth. The plaintiff alleges that the dentist had maliciously extracted the tooth, but it is said that the testimony showed that the patient was taken to the dentist's office by his father, that he pointed out the tooth to the dentist, and that the latter had by mistake extracted another tooth.

Dr. William H. Egle, genealogist and historian, died February 19, at Harrisburg Pa. He was graduated from the Medical Department of the University of Pennsylvania in 1859. In 1863 he was appointed surgeon of the Forty-seventh Pennsylvania Regiment, and served until December, 1865. In March, 1887, he was appointed State Librarian, which position he held for 12 years. He was the author of a history of Pennsylvania, and a large number of other historical publications.

Free Hospital for Consumptives.—The Committee on Appropriations at Harrisburg, has decided to recommend \$50,000 for the establishment of a free sanitarium at White Haven, near Glen Summit. The appropriation, it is proposed, shall be made available in two annual installments of \$25,000 each. These recommended appropriations will be in addition to the original award of \$10,000 for the treatment of incipient cases, endorsed by the Legislative Committee having in charge the apportioning of the State's funds.

Philadelphia Neurological Society.—At the stated meeting to be held February 25, at 8.15 P.M., in the hall of the College of Physicians Drs Wm. H. Zeller and F. X. Dercum will exhibit **A case of astereognosis** and Drs. GEORGE L. WALTON and WALTER E. PAUL, of Boston, will, by invitation, read a paper entitled **Astereognosis, with illustrative cases.** The presence of members of the profession is cordially invited. At the close of the meeting a reception will be tendered Drs. Walton and Paul at the University Club.

Medical Alumni Meet.—The Philadelphia Alumni of the Medical Department of the University of Pennsylvania met February 16 at the Bourse, and heard a lecture given by Ernest W. Kelsey, of the Class of '94, in association with William C. Henderson, detailing two years' experience in the Alaska gold fields. The lecture was illustrated with lantern slides. A communication was received from Provost Harrison advising the appointment of a committee to consider the best way of raising funds for the building and endowment of a new medical laboratory. A committee will be appointed by the executive board of the association.

The Rush Hospital.—The annual meeting of the corporation of the Rush Hospital for Consumption and Allied Diseases, of Philadelphia, was held February 19. There was no opposition to the reelection of the old board of officers, as

follows: President, Hon. William N. Ashman; secretary, Nathaniel E. Janney; treasurer, E. A. Sobernheimer; trustees, Jeremiah J. Sullivan, Samuel Castner, Jr., Rev. Thomas J. Barry, Frank Read, Dr. James Tyson, Miss Mary S. Buckley, Barclay H. Warburton, W. H. Staake, George W. Farr, Frank A. Sobernheimer, Edmund G. Hamersly, Emma A. Duffield, Mrs. George Pierce and Kenneth M. Blakiston.

Berks County Medical Society.—At the February meeting of the society Dr. HUNSBERGER, of Blandon, read a paper on **Delirium tremens**, in which he compared the symptoms in a measure to uremic poisoning. When diaphoresis could be established the patient improved. He cited a number of instances of men who were heavy and constant drinkers, who did not have the delirium simply because they were working before a hot blast furnace, which caused them to perspire very freely, and thus to unload the poison by the skin. His plan of treatment is rest in a dark room, diaphoresis, purgation, diuretics, hydrate of chloral, only in a few doses early, and digitalis in a few doses. Bromides of potassium and sodium and morphia to produce sleep if necessary.

Vital Statistics of Philadelphia for the week ended February 16, 1901:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 3, bladder 1, brain 12, bronchi 13, kidneys 21, lungs 94, peritoneum 4, pleura 3, stomach and bowels 17, spine 2		170
Inanition 17, marasmus 8, debility 4		29
Tuberculosis of lungs		68
Apoplexy 25, paralysis 8		33
Heart—disease of 33, fatty degeneration of 3, Uremia 12, diabetes 2, Bright's disease 12		36
Carcinoma of stomach 4, uterus 2, liver 2, pancreas 1, rectum 1		26
Convulsions 11, puerperal 1		10
Diphtheria	91	12
Brain—softening of 2, congestion of 2, disease of 2		11
Typhoid fever	61	6
Old age		7
Suicide		17
Alcoholism		5
Cyanosis		2
Scarlet fever	62	7
Influenza 16, aneurysm of aorta 2, asthma 2, casualties 5, congestion of lungs 3, childbirth 2, cirrhosis of the liver 2, croup 3, membranous croup 3, diarrhea 2, dropsy 1, dysentery 2, epilepsy 1, erysipelas 4, hemorrhage from stomach 1, from uterus 1, hernia 2, leukemia 1, poisoning 2, arterial sclerosis 2, spine 1, shock 2, septicemia 3, suffocation 2, whooping-cough 3		10
		73

County Medical Society.—The treatment of tuberculosis of the glands of the neck with minimal scarring, by Dr. G. BETTON MASSEY, was the first paper at the meeting of February 13. Because of the author's illness the paper was read by Dr. E. R. KIRBY. The method is offered as a substitute for cutting operations, which leave unsightly scars and is a modification of the cataphoric method for treating cancer. The destruction of the tubercle bacilli by nascent oxychloride of mercury is the principle upon which the operation is based. A small opening is made through the skin and the wound cauterized sufficiently to keep it open for drainage. Through this opening is introduced, at intervals of a few days, a gold electrode amalgamated to hold as much mercury as possible. A current of 2 to 10 milliamperes is passed for 10 minutes. The sinus drains the products of the dead bacilli. Two cases of cure by this method were reported. The resulting scar is a mere point. Dr. J. H. GIBBON said that two points seemed worthy of comment. The first is that tuberculous glands are rarely single and unless the results of this treatment extend to others than the one to which application is made its efficacy is not assured. Again, simple drainage often causes such glands to shrink without any applications. Dr. HAMMOND believes the condition is one which should not be irritated by such a method. The capsule is broken down and spreading of the process is more likely. The tuberculous process can be spread by the caseous matter formed, as well as by the bacilli themselves.

Dr. A. R. MOULTON reported a case of **Rupture of the rectum and hernia of the intestine in an insane man.** The patient was a man of 34, an inmate of the Pennsylvania Hospital for the Insane, who had induced a rectal prolapse by means of his hands. On November 20, 1900, the rectum ruptured and a loop of small intestine and mesentery, 2 feet in length, protruded. Shock was profound and death followed in 36 hours.

Pathological Society.—The meeting of February 14 was opened with a paper by **DR. ALBERT WOLDERT**, who showed **original specimens of zygotes of estivo-autumnal malarial parasites in the middle intestine of the mosquito.** Specimens of the **anopheles** were secured from breeding places within the city limits, allowed to bite patients having malaria, and were then dissected after 4 or 5 days. After several unsuccessful trials, zygotes were found. Search for mosquitoes showed that the **anopheles** was present in every locality where malaria was endemic, but was also found where there was no malaria, one such place being in the Pocono Mountains, 3,000 feet above sea level.

DR. D. L. EDSALL read a paper on **The diagnosis of pancreatic disease by the estimation of the urinary sulphates and of the fecal fat.** Two cases were reported. In one case there were stomach symptoms, jaundice, and other signs of pancreatic disease. Examination of the urine showed that the ethereal sulphates were less than half the normal quantity, the ratio between the ethereal and the preformed being 1 to 20 or 29, instead of 1 to 10. Autopsy showed carcinoma of the head of the pancreas. In the second case the ethereal were above normal. The patient recovered apparently having had only an attack of catarrhal jaundice. The estimation of the sulphates is of real value only when a positive result is obtained. When the test is negative, very little attention should be paid to it. When positive it is not of much value if the patient be on restricted diet. It is also to be considered in relation to the conditions which so often accompany pancreatic disease—constipation, icterus, cachexia, etc. These all tend to increase the sulphates. A decrease when these conditions are present is of diagnostic importance. Indicanuria is not considered of diagnostic value in any disease. Regarding the presence of fat in the stools there is a widespread belief among students and even practitioners that this means pancreatic disease. This is not true, as there is fat in normal stools. The importance of icterus as a cause of fatty stools was emphasized. In the second case before mentioned the stools contained a very high percentage of fat. The conclusion reached is that fatty stools are not of much importance in proving the existence of pancreatic disease. **DR. WADSWORTH** believes that indican is of value as a sign and the short time needed to make the test is in its favor. The formation of sulphates is dependent on a catarrhal coating of the intestine. The amount of fermentation present depends on the rate of motion in the intestines. Sluggish motion of the intestines, catarrhal coating, etc. must be taken into account when studying liver or pancreatic disease.

DR. JAMES H. LLOYD reported a case of **Extensive sinus thrombosis caused by long-standing middle ear disease.** The case was reported as one unusual in its etiology, symptomatology, and pathology. The patient was a woman of 34, who had been deaf in both ears since an attack of measles in early childhood. The case was an obscure one, having been sent to the hospital as one of typhoid fever, autopsy showed a chicken-fat clot in the right lateral sinus.

DRS. J. H. GIRVIN and J. D. STEELE reported a **carcinoma of the pleura diagnosed by tissue removed in tapping.** The patient is a woman of 50 who had pleurisy 3 years ago. There are now lumps in the right breast and the axillary glands are enlarged. Tapping removed 27 ounces of bloody fluid and a long thin piece of tissue, which on examination proved to be carcinoma.

DR. RANDLE C. ROSENBERGER showed specimens from a **sarcoma of the mediastinum of a rhinoceros.** The animal had died recently in Zoological Gardens, presumably of old age, as it was nearly 100 years old. Examination showed a small round cell sarcoma of the mediastinum. It had caused no symptoms and no metastasis was noted.

NEW JERSEY.

State Board of Health.—The New Jersey State Board of Health is considering the advisability of disinfecting the books used in circulating libraries of that State, and has decided that they must be fumigated at regular intervals.

Atlantic City Medical Society.—At the annual meeting the following officers were elected: President, Dr. Theodore Boysen, of Egg Harbor City; vice-president, Dr. W. K. Darnall; secretary and treasurer, Dr. Theodore Senseman; reporter, Dr. A. B. Shimer.

Smallpox in Woodbury.—The appearance of smallpox in this city has occasioned a feeling of alarm among the residents. Two cases are reported, remote from each other. Both patients are school boys. A special meeting of the Board of Health and Board of Education was held, and it was decided to recommend a general vaccination.

NEW YORK.

Appointment.—Dr. Daniel W. Marston has been appointed visiting surgeon to the Randall's Island Hospital, by the New York Department of Public Charities.

Red Cross Hospital.—The sum of \$100,000 raised by private subscription has been used to purchase a plot of ground in New York City on which a Red Cross Hospital and Home for Red Cross Sisters will be erected. The additional \$60,000 required to build the hospital and home will be raised in the same way.

New Mount Sinai Hospital.—Preliminary and foundation plans for nine new hospital buildings, to be erected for Mount Sinai Hospital, on the block bounded by Fifth Avenue, Madison Avenue, One Hundredth and One Hundred and First Streets, were submitted to the Department of Buildings. The buildings will be built of brick, with terracotta trimmings, and have been estimated to cost \$1,600,000.

German Hospital.—The thirty-first annual report of the Board of Trustees of the German Hospital and Dispensary of New York City states: During the past year, according to the report, 3,352 patients were treated at the hospital. Of these 2,447 were free patients. In the dispensary 22,595 patients received treatment free of charge. The expenses at the hospital amounted to \$79,405, making an average of \$1.20 a day for each patient. During the year the hospital received \$10,047.50 in legacies and \$4,963.80 in donations.

Albany Hospital for Incurables.—A tract of land was purchased recently by the trustees of the Albany Hospital for Incurables. The modern pavilion system connected by corridors will be utilized. The work has been incorporated under the direction of Messrs. M. T. Hun, L. G. Hun, Wheeler B. Melius, Daniel Casey, with the approval of Judge William L. Learned. The incorporators are William H. Murray, M.D., Robert Geer, John W. McNamara, John H. Farrell and Charles N. Phelps.

New York Neurological Society.—Stated meeting February 5, 1901. Dr. Joseph Collins, President.

A Case of Locomotor Ataxia Trained by the Fraenkel Method.—**DR. A. WIENER** presented this man. He had been under this system of training for about one year, and while ataxia was still present, he had been very greatly improved, and was now able to go about even at night unaided. There had been no other treatment for the tabes.

Sarcoma of the Brain.—**DR. A. WIENER** also presented a pathological specimen from a person, 17 years of age, who had first come to him about November 1, 1898. There was an absolutely negative history of alcoholism and syphilis. About 2 years before this time the patient had suffered from a severe fright, and almost immediately thereafter had had a severe convulsion. Nothing further had been noticed until the summer of 1898 when she had suddenly developed a difficulty of speech, with right facial palsy. She had suffered from bad headaches frequently for 3 months previously. On coming under observation, there had been excruciating pain over the occipital region, complete deafness in the right ear and a bulging of the tympanic membrane. The right sterno-

mastoid muscle had been in a state of constant contraction, and there had been a double optic neuritis, most marked on the right side. The voice was hoarse. Neither the upper nor the lower extremities had suffered any loss of power. There was no swaying when the eyes were closed, nor was there any bladder trouble. Her temperature was 100° F. The seventh, eighth, ninth, tenth, eleventh and twelfth nerves were affected on the right side, and the sixth nerve on the other side. On November 8, a slight ptosis had been noticed, and the twelfth nerve palsy had become more marked. On November 28, there had been vomiting, vertigo and an increase in the ptosis of the left eye. On December 8 there had been complete third nerve palsy on the left side, and the headache had been very severe. Having diagnosed a tumor of the brain, the patient had been sent to the Mt. Sinai Hospital. A mass had developed behind the ear, and on aspirating this it had been found that the case was one of congenital sarcoma. On January 11, 1899, the third palsy had entirely disappeared on the left side, and the swelling behind the ear had grown larger. On January 21, the patient had suddenly become confused and blind in both eyes. In April it had been decided to open the mass to relieve the pain. By June 30 the patient had been up and around again. In October there had been a complete brachial plexus palsy on the right side. The tumor had kept on growing until almost the size of the patient's head. The patient had died on February 2, 1901, and an autopsy had been performed. The whole tumor had been found below and outside of the brain. In front was a large giant-cell sarcoma which had completely destroyed the sphenoid bone. At the back the tumor had destroyed the occipital bone. The brain was exhibited, and it showed that only the pons had suffered pressure. The tumor had apparently started in the mastoid portion of the temporal bone.

Tendon Transplantation for Deformity of the Hand.—DR. W. R. TOWNSEND presented a case of this kind, which had been exhibited to the society about 1 year ago. It was a case of infantile cerebral palsy. Instruments had been used at the time of birth, but no damage had apparently been done to the exterior of the skull. He had never been able to use his right hand, and it was a typical "claw-hand" when the boy came under observation at the age of 15 years. On December 21, 1899, an incision had been made over the wrist, exposing the tendons. The flexor carpi radialis, the flexor carpi ulnaris, and the palmaris longus were divided just above the annular ligament. The hand was then turned over and an incision made on the dorsum of the wrist, and the extensor communis digitorum exposed. A dissection having been made through the interosseous space, the extensor tendon was pushed through, and being too long, was doubled upon itself. It was then attached to the tendons previously mentioned. The union of the tendons had been satisfactory and permanent. The tendons had not shown any tendency to unite to the surrounding tissues. He was now able to write fairly well, whereas formerly he could not even grasp a pen. DR. B. SACHS said that he had been deeply interested in this subject, and it was certainly the best procedure that had been suggested for these cases of contracture whether of spinal or cerebral origin. The problem was to split the tendon of the over-acting muscles and unite them to the tendons of the under-acting muscles, and so restore the equilibrium of power. It had been found prudent not to allow the patient to exercise much or to use electricity until the tendinous union had become very firm. It was unfortunate that this boy was not able to extend his fingers, yet he had secured good extension of the wrist. In spite of the tendon transplantation the boy experienced no difficulty in producing flexion when he desired to do so. DR. SCHLAPP remarked that it seemed to him that the boy's hand was decidedly larger now than when he had seen the case a few months ago.

DR. CREIGHTON presented a young woman of neurotic temperament who, 4 years ago, had had hysteria and typical attacks of **grand mal**. One year ago she had had the grip, followed by pneumonia, and this had been followed by headaches, aching spine, and numbness in the left side. There were severe contractures in the left arm. A small painful tumor had appeared in the left palm, and had been removed by the family physician under cocaine. It had returned and had been again removed. A galvanic current of 10 milliamperes had brought out a slight redness on the palm. Three

days before menstruation a large red spot had appeared on the back of the forearm, and soon afterward several similar spots had made their appearance on the arm. A few days before the next menstruation these spots had returned, and in addition, a number of large blotches on the left shoulder, and on that side of the neck. The whole side was very hyperæsthetic. There was slight narrowing of the visual field, and there was left-sided sweating. The speaker said that the case was very similar to one recently reported from Erb's clinic. DR. JOSEPH FRAENKEL asked whether there had been a history of malaria, and whether the case might not be looked upon as one of morphea. DR. CREIGHTON replied that there was no history of malaria, and the family physician had stated that the tumor which he had removed grew on the nerve. The microscopical examination had been made at the laboratory of the Presbyterian Hospital, and the report had been that there was a slight round-cell infiltration only; no nerve degeneration was found. The thyroid gland was not enlarged. DR. C. L. DANA said that he had seen cases presenting just this appearance, but entirely free from hysteria. DR. W. B. NOYES said that 4 or 5 skin lesions were closely associated with nervous troubles. Herpes zoster, erythema multiforme, Reynaud's disease, all were distinctly related to the nervous system, yet it was very difficult to state the exact relation. It had occurred to him that the element of suggestion regarding the connection with the nerve might be responsible for some of the phenomena present. DR. E. D. FISHER said that this could not properly be described as simple hysteria, or as the result of mere suggestion. The eruption was not characteristic of an hysterical state. DR. M. G. SCHLAPP said that these cases had been described before; they had been brought on by suggestion. In this case an injection had been given in the arm, and shortly afterward this dermatitis had first appeared. The eruption was not characteristic of any particular skin lesion, but it closely resembled cases that had been described as hysterical skin manifestations. In typical zoster there was frequently a degeneration of the nerve fiber itself.

DR. SACHS said that the case was a very unusual one, and he did not regard it as belonging to the class of hysterical hyperemia. It was certainly a distinct form of skin neurosis. The closest resemblance in the anatomical distribution was to herpes. DR. JOSEPH COLLINS said that if the girl should develop a pneumonia he would not be willing to call it a hysterical pneumonia; neither was he willing to call this a hysterical skin disease. He was inclined to think it was closely related to morphea. DR. CREIGHTON said that a case had been reported very recently in which the gangrenous form had ultimately developed. This case had been described as hysterical. DR. J. C. JOHNSTON, the dermatologist, had seen this patient and looked upon her as hysterical.

Paralysis of the Spinal Accessory.—DR. PEARCE BAILEY read this paper. He said that the chief interest of this nerve was surgical. Within the past year two instances had come to his notice of accidental section of the nerve. In most cases the paralysis which results from section was not particularly disabling, but such had not been the case in the instances referred to. When the sternomastoid was completely paralyzed the freedom of movement of the head was interfered with, but not totally abolished. In the two cases referred to the disability had been unusually great, and had led him to study more carefully the nerve supply. It was now regarded as a spinal nerve, pure and simple. The spinal portion of the nerve, represented by the external branch, springs from the upper five segments of the cord. Paralysis of the nerve presents a varying symptomatology according to the site of the lesion. An injury outside of the skull to cause symptoms referable to both branches must be situated directly at the base of the skull. The extracranial lesions of the spinal accessory are confined to the external branch, and are nearly always traumatic. Neuritis in this nerve is rare. A case was cited to illustrate the possible traumatic origin of spinal accessory palsy by injury with a blunt instrument. In two other cases reported the paralysis had been directly the result of operation. In the second case the resulting incapacity had been so great that the right arm had been rendered practically useless for any heavy work. Neurorrhaphy had been performed about six weeks after the operation at which the nerve had been injured, and the ends of the divided nerve had been found separated over one inch. The improvement in motor power had been slow. A reference to the literature showed conflicting views re-

garding the nerve supply. Dr. Bailey said that the spinal center between the first and fifth cervical segments of the cord was fixed and constant, but occasionally all the axons pass to the muscle by the spinal accessory. Under these circumstances the motor impulses reach the trapezius through the spinal accessory, and hence, section of it means total palsy. Dr. W. M. LESZYNSKY said that he had seen a patient two months ago who had been operated upon for torticollis. Over 1 inch of spinal accessory nerve had been removed on the left side without relief, and the function of the muscle had remained perfectly normal. He had seen over an inch of the other spinal accessory nerve removed subsequently, yet the muscle had not been affected at all; hence he had held that it was useless in these cases of spasm to operate upon the spinal accessory nerve. Dr. J. ARTHUR BOOTH said that he had had a case of spasmodic torticollis operated upon by section of the spinal accessory nerve. A little more than one inch had been excised, and the sternomastoid and part of the trapezius had been paralyzed as a result.

Congress of Nurses.—An international congress of nurses will be held in Buffalo next September to strengthen the national and international organizations which the nurses of this country, Great Britain, the English colonies, Denmark, and Holland have for the last few years been intent upon developing. All these countries have now national organizations of nurses, based upon the principles of self-government and mutual agreement, pledged to uphold the honor and best interests of their profession, and to work for a steadily advancing educational standard and ethical development. The national association of the United States has become affiliated with the National Council of Women, as the others purpose doing in their respective countries. The president of the International Council is Mrs. Bedford Fenwick, of London, and the vice-presidents are the presidents of the respective national councils. The chairman of the congress will be Miss McIsaac, superintendent of nurses in the Illinois Training School, Chicago, and the secretary is Miss Banfield, superintendent of the Polyclinic Hospital, of Philadelphia.

CHICAGO AND WESTERN STATES.

Dr. John Madden, professor of physiology, Milwaukee Medical College, has resigned.

Dr. Murphy has been appointed oculist to the Chicago, Milwaukee, and St. Paul Railway at Mason City, and also to the Mason City and Clear Lake Railway.

Dr. W. A. Jones has succeeded Dr. Alexander J. Stone, as editor of the *Northwestern Lancet*. The office of publication has been transferred to Minneapolis.

Visiting Nurses.—During the month of January, 4,287 visits were made by the nurses of the Visiting Nurses' Association of Chicago. This is the largest number ever cared for by the association.

New Medical Registration Board.—A new State Board of Medical Registration has been appointed in Michigan—Drs. Joseph B. Griswold, Grand Rapids; George E. Ranney, Lansing; Walter H. Sawyer, Hillsdale; Austin W. Alvord, Battle Creek; Henry B. Landon, Bay City, and five from other schools of medicine.

The Western Ophthalmologic and Otolaryngologic Association will meet in its next annual session in Cincinnati, Ohio, April 11 and 12. A fine program has been arranged and the medical profession are cordially invited to attend the sessions. Dr. C. R. Holmes, of Cincinnati, is chairman of the local committee of arrangements. Dr. M. A. Goldstein, of St. Louis, is the president, and Dr. W. L. Ballenger, of Chicago, is secretary.

Union State Hospital.—The stockholders of the Union State Hospital, Indianapolis, held their annual meeting and elected the following directors: Deborah Moore, John H. Holliday, Gen. Benjamin H. Harrison, Louis Hollweg, H. H. Hanna, S. P. Sheerin, T. C. Day, Victor Hendricks, Albert Lieber, Nathan Morris, and Bement Lyman. The financial

and hospital reports were submitted and approved. The directors elected the following officers: President, H. H. Hanna; vice-president, John H. Holliday; treasurer, Bement Lyman; secretary, Deborah Moore.

Medical Examination Before Marriage.—*The Cleveland Journal of Medicine*, February, 1901, states a bill providing for a board of medical examiners to decide upon the fitness for marriage of all applicants for marriage license has been introduced in the Colorado House of Representatives. The bill provides that the license may not be issued unless the medical board recommends it. The board is to sit 10 days in every month. A number of diseases and certain defects in family records are declared to be bars to marriage in Colorado after passage of this act. The fee for the examination is fixed at \$15.

Refuse Further Attendance.—Prisoners at the county jail, St. Joseph, Mo., are without medical attention by reason of the increasing numbers of smallpox patients there, which caused the attending physicians to give up the task of stamping out the disease. Sheriff Spencer has further complicated matters by issuing an order that he would permit no more patients to be removed from the jail to the pest-house unless more guards were placed at the latter point. By reason of the few guards at the pest-house a number of desperate men who are now infected with the disease might make their escape if removed from the jail. An additional pest-house will, in all probability, be built during the next few days.

SOUTHERN STATES.

Virginia State Board.—A bill passed the Senate recently which directly affects all the students of this State. Dr. LeCato introduced the measure which provides that when a medical student has passed an examination on any subject before the State Board, he shall have credit for it even if he fails in other branches at the same time.

Cancer Home.—A new home for the treatment of incurable cancer will shortly be opened in Maryland for the benefit of the poor, through a gift made by Mrs. Rose Hawthorne Lathrop to the Servants of Relief for Incurable Cancer. It is specifically stated that the corporation shall use the donation only as a free home for the poor persons suffering from incurable cancer.

Gulf Coast Medical.—At the reorganization of the Gulf Coast Medical Society, at Scranton, the following officers were elected for the ensuing term: Dr. B. F. Duke, of Pascagoula, president; Dr. J. J. Washington, of Pass Christian, vice-president; Dr. J. N. Rape, of Moss Point, secretary and treasurer. The next meeting will be held at Pass Christian on May 1.

CANADA.

Against Tuberculosis.—A conference has been called by the Governor-General of Canada, urging all governments to adopt organized methods for diminishing the spread of tuberculosis.

French-Canadian Medical Congress.—The French-Canadian physicians of Quebec are organizing a medical congress of the French practitioners of North America, to be held next summer. The French practitioners of Louisiana have expressed their intention of attending.

MISCELLANY.

Practising Without License.—Three Chinese doctors have been arrested in Kansas City for practising medicine without a license.

Supernumerary Digits.—An infant has recently been born in Cincinnati with 6 toes on each foot, and with 6 fingers on the right hand and 7 on the left.

Dr. Chapot Prevost, who performed the operation on the xiphopagus, has been awarded a sum amounting to about \$4,000 as a prize by the Brazilian government.

Obituary.—DR. N. H. RIDDICK, at Norfolk, Va., on February 14, aged 50 years.—DR. J. W. ELLIOT, at Yazoo City, Miss., on February 14.—DR. THOMAS FRIDGE MURDOCH, at Baltimore, Md., on February 18, aged 72 years.—DR. H. B. POTTER, at Orleans Four Corners, N. Y., on February 18, aged 61 years.—DR. JOHN M. THOMAS, at Corry, Pa., on February 19, aged 75 years.—DR. WALWORTH MARSH, at West Point, Miss., on February 15, aged 29 years.—DR. GEORGE L. KIRBY, Superintendent of the State Hospital at Raleigh, N. C.

Election of Officers.—The following officers were elected in the national societies which recently met in Baltimore: American Psychological Association—Professor Josiah Royce, president; Dr. Livingston Farrand, secretary. Society for Plant Morphology and Physiology—Dr. Edward F. Smith, president; Professors F. C. Newcombe and L. M. Underwood, vice-presidents; Professor W. F. Young, secretary and treasurer. American Morphological Society—Professor J. S. Kingsley, president; Professor E. A. Andrews, vice-president; Professor T. H. Montgomery, Jr., secretary. American Association of Bacteriologists—Professor William H. Welch, president; Professor E. O. Jordan, vice-president; Professor H. W. Conn, secretary and treasurer.

Health Reports.—The following cases of smallpox, cholera, and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended February 16, 1901:

SMALLPOX—UNITED STATES.

Changes in the Medical Corps of the U. S. Army, for the week ended February 16, 1901:

DUTCHER, First Lieutenant BASIL H., assistant surgeon, having been discharged from hospital in Manila, will return to his station at Tayu, Pangasinan.

The following named acting assistant surgeons are authorized to proceed to Manila and report to the president of the Army medical board, for examination for appointment as assistant surgeons. Department of Northern Luzon—GEORGE M. EKWURZEL, ISIDOR M. UNGER, ERNEST F. SLATER, LOREN B. OHLSOBER, JAMES F. EDWARDS, and U. S. GRANT DEATON; department of Southern Luzon—FRANK T. WOODBURY and WILMOT E. BROWN; department of the Visayas—PAUL R. FLETCHER.

STEPHENSON, Major WILLIAM, surgeon, will report to the commanding general, department of Southern Luzon, for assignment to duty.

MUNSON, Captain EDWARD L., assistant surgeon, is granted leave of absence for 2 months on account of sickness.

BECHEE, MAX A., acting assistant surgeon, will proceed from Los Angeles to San Francisco, Cal., for assignment to duty with troops en route to the Philippine Islands, where he will report to the commanding general, division of the Philippines, for assignment to duty.

SANTOIRE, H. A., acting assistant surgeon, is granted leave of absence for 1 month from about February 18.

The following named dental surgeons will proceed from the places designated to Washington, D. C., and report to the Surgeon-General of the Army for instructions: JOHN S. MARSHALL, Chicago, Ill.; ROBERT T. OLIVER, Indianapolis, Ind.

IRA E. GATES, GEORGE GRIFFITH, BENJAMIN HANSON, JAMES SWEENEY, PAUL H. WEYRAUCH and AMOS A. CARTER hospital stewards (appointed February 8 from privates of the hospital corps) now in Manila, P. I., are assigned to duty in the division of the Philippines.

FREDERICK W. BOSCHEN, AUSTIN G. BARBER, LOUIS FRANK, FRANK LUVE, HERBERT SHARMAN, PAUL L. STANGL, AUGUST J. STROMBERG, DON D. WILLIAMS, THOMAS J. WALKER, JOSEPH WATERS, GUSTAVE FONTEENE, WILL G. BUTLER and HARRY MEADE, hospital stewards (appointed February 8 from acting hospital stewards of the hospital corps) now at Manila, P. I., are assigned to duty in the division of the Philippines.

MORGAN, ROBERT W., dental surgeon, will proceed from Lynchburg, Va., to Washington, D. C., and report to the Surgeon-General of the Army, for instructions.

ARTHUR, Major WILLIAM H., surgeon, will proceed to Dagupan, province of Pangasinan, and assume command of the military hospital at that point.

SCHREINER, First Lieutenant EDWARD R., assistant surgeon, will proceed to San Isidro, province of Nueva Ecija, and report to the chief surgeon, Fourth division, for duty at the hospital at that point.

PENROSE, Major GEORGE H., surgeon, upon report of medical examining board, will proceed to San Francisco, Cal., and report to the adjutant-general of the Army, with a view to discharge by reason of disability.

The following named medical officers, now at stations designated, will report on the day of arrival at the Presidio of volunteer troops from the Philippine Islands, to the chief mustering officer for temporary duty to make the medical examination of officers and enlisted men belonging to volunteer regiments, required by G. O. 124, series 1893, H. Q. A., and other existing regulations: Major ROBERT J. GIBSON, surgeon, San Francisco, Cal.; Acting Assistant Surgeon CHARLES H. ANDREWS, Army General Hospital, Presidio; Acting Assistant Surgeon FRANK A. E. DISNEY, Presidio. This duty will be performed by Major Gibson, surgeon, in addition to his other duties at these headquarters, and he will make immediate request for such clerical assistance, accommodations, materials and appliances as may be needed in the work to be performed by the medical officers under this order.

LATIMER, CHARLES H., acting assistant surgeon, will proceed to his home, Washington, D. C., for annulment of contract.

JAMES, WILLIAM F., acting assistant surgeon, is granted leave of absence for 1 month.

PITCHER, GEORGE S., acting assistant surgeon, will proceed to his home, Portland, Me., for annulment of contract.

PROMOTIONS.

To be assistant surgeons, with rank of captain—CLARK I. WERTENBAKER, Ohio; FRANK A. E. DISNEY, New York; CHARLES H. ANDREWS, New York; ROBERT H. ENDERS, Sr., Arkansas; MATTHEW LEPPER, Missouri; CHARLES ANDERSON, California; JAMES S. KENNEDY, Pennsylvania, all acting assistant surgeons, U. S. Army; FRANK P. KENTON, Kentucky, late major and surgeon Fourth Kentucky Volunteers; GUY G. BAILEY, Michigan; GEORGE A. MCHENRY, Mississippi; EDWARD F. HORB, New York; SHANNON RICHMOND, Missouri; ELMER S. TENNET, New Hampshire; SAMUEL D. HUNTINGTON, California, all acting assistant surgeons, U. S. Army; JAMES J. ERWIN, Ohio, captain and assistant surgeon Thirtieth Infantry; JAMES F. PRESNELL, Iowa; FREDERICK H. SPARENBURGER, New Jersey; IRVIN E. BENNETT, Pennsylvania; JAMES H. MCCALL, Tennessee, all acting assistant surgeons, U. S. Army; THOMAS C. STONEKARD, Indiana, late major and surgeon One Hundred Fifty-ninth Indiana Volunteers and acting assistant surgeon U. S. Army; HAROLD W. COWPER, New York; DWIGHT B. TAYLOR, Ohio, all acting assistant surgeons, U. S. Army.

To be assistant surgeons, with rank of first lieutenant—February 4—ARTHUR W. MORSE, Illinois, vice POLHEMUS, promoted; FRANK C. BAKER, District of Columbia, vice BORDEN, promoted; HENRY S. KIERSTED, Pennsylvania, vice MEARNS, promoted; ALLIE W. WILLIAMS, Georgia, vice EDIE, promoted; JOHN J.

REILLY, New York, vice CROSBY, promoted; JEROME STEWART CHAFFEE, New York, vice KNEEDLER, promoted.
To be assistant surgeons of Volunteers, with rank of captain—HARRY A. LITTLEFIELD, Oregon, late acting assistant surgeon, U. S. Army, February 9; FREDERICK W. COX, S. Dakota, late captain and assistant surgeon First South Dakota Volunteers, February 9; GERRY S. DRIVER, District of Columbia, acting assistant surgeon, U. S. Army, February 9; JUSTUS M. WHEATE, Indiana, acting assistant.

Changes in the U. S. Marine-Hospital Service, for the week ended February 14, 1901:

SAWTELLE, H. W., surgeon, granted leave of absence for 30 days from February 20. February 14.
KALLOCH, P. C., surgeon, granted leave of absence for 3 days from February 17. February 8.
GEDDINGS, H. D., passed assistant surgeon, granted leave of absence for 8 days from January 26, on account of sickness. February 12. Granted leave of absence for 30 days from February 3. February 12.
GARDNER, C. H., passed assistant surgeon, granted leave of absence for 7 days. February 11.
PARKER, H. B., assistant surgeon, to proceed to Gulf Quarantine and assume temporary command of the service during the absence on leave of the medical officer. February 8.
MOORE, DUNLOP, assistant surgeon, to proceed to Port Townsend, Wash., and assume temporary command during the absence on leave of the medical officer in command. February 11.
McCOY, G. W., assistant surgeon, granted leave of absence for 14 days from March 13. February 12.

Changes in the Medical Corps of the U. S. Navy, for the week ended February 16, 1901:

BAGG, C. P., passed assistant surgeon, detached from the Cavite Naval Station and ordered to the "Culgoa."
ALFRED, A. R., passed assistant surgeon, detached from the "Culgoa" and ordered to the Naval Station, Cavite, February 7.
BIDDLE, C., surgeon, detached from the Naval Hospital, Norfolk, Va., and ordered home and to wait orders.
LEWIS, D. O., surgeon, detached from the "Iowa" and ordered to the "Philadelphia," February 13.
ARNOLD, W. F., surgeon, detached from duty at the Naval Recruiting Rendezvous, Chicago, Ill., March 1, and ordered to the "New Orleans," sailing for Manila, March 15.
GRIFFITH, S. H., surgeon, detached from the "Prairie" when put out of commission, and ordered to duty under the Bureau of Medicine and Surgery.
CORDEIRO, F. J. B., surgeon, detached from the "New Orleans" and ordered home and to wait orders.
MOORE, A. M., surgeon, retired, ordered to duty at Naval Recruiting Rendezvous, Chicago, Ill., March 1.

Foreign News and Notes.

GREAT BRITAIN.

Mr. T. P. Legg, M.B.Lond., F.R.C.S., has been appointed assistant surgeon to the Royal Free Hospital.

Election.—Dr. Martin J. P. Dempsey, F.R.C.P.I., visiting physician to the Mater Misericordiae Hospital, Dublin, has been elected to the chair of materia medica and pharmacy in the Catholic University School of Medicine, rendered vacant by the death of Dr. F. J. B. Quinlan.

Cancer Laboratory.—A research laboratory has been opened in connection with the Middlesex Hospital, London, England, which is to be entirely devoted to the care and investigation of cancer. In the hospital are 60 inoperable cases, which will be under close scientific observation.

Enteric Fever Among British Troops.—The Secretary of State for War gave a statement of the increasing number of cases of enteric fever among the troops in South Africa. In October there were 569 cases and 98 deaths; in November, 1,213 cases and 207 deaths; and in December, 1,665 cases and 286 deaths. The total since the beginning of the war to December is 19,101 cases and 4,233 deaths.

CONTINENTAL EUROPE.

Dr. G. Holzknecht has been appointed Röntgen-ray expert in Vienna.

Pirogoff Congress.—The Eighth Pirogoff Congress will be opened in Moscow in December, 1901.

Plague Steadily Spreading.—There were 922 deaths from the plague in Bombay during the past week.

Physicians Rewarded.—The Czar's physicians who were in attendance upon him during his recent attack of typhoid fever, have been rewarded. Prof. Leo Popoff has been appointed body physician to the Czar, Dr. Tichskonoff honorary physician to the imperial family, and upon Dr. Hirsch has been conferred the order of Alexander-Nevski.

Autopsies on Suicides.—Professor Meller, of Kiel University, the renowned expert in mental diseases, made autopsies on 300 suicides in 5 years, and now states that he found the brains of 43% showed distinct malformation; 29% of the remainder were suffering at the time of their death from acute febrile inflammation; 143 of the aggregate had organs diseased by alcoholism.

Cheap Modes of Transportation Responsible for Obesity.—The multiplication of cheap modes of transport, in the opinion of the *London Medical Press and Circular*, favors the tendency to obesity, so that with the rapid development of underground and surface electric traction in London and other large cities the next generation must look out for an increase in the number of stout individuals.

Bubonic Plague.—The *Daily Mail* publishes the following from its St. Petersburg correspondent: Serious reports are in circulation here regarding the outbreak of what was first called "hunger typhus," but is now officially admitted to be bubonic plague in the Khirgiz steppes of western Siberia. Many thousands have died. The Government is sending out large quantities of wheat to be distributed to the starving population and is organizing traveling medical services to localize the outbreak.

The Influence of Neurectomy upon the Union of Fractures.—B. G. Muscatello and D. Damascelli (*Archiv f. klin. Chir.*, Bd. 58, H. 4.) after many experiments come to the conclusion that fractured bones may unite independent of influence from the nervous system. It had been believed that when nerves were cut in cases of experimental fracture, that the results were delayed ossification, larger and softer callus, and frequently the formation of pseudoarthroses. Experimenting upon guineapigs the authors fractured the ulna, but left the radius intact, the latter acting as a protection. At the same time they resected a portion of the brachial plexus. [M.B.D.]

The Relation of Appendicitis to Diseases of the Uterine Appendages.—In a paper read before the N. Y. State Medical Society, January 29-31, 1899, Dr. Albert Beahan says: The occurrence of right side pelvic disease when the question arises as to the diagnosis between disease of appendix and appendages, is frequent, and sometimes requires fine distinction. Gross changes in the appendages resulting from disease coexisting with appendicitis are not uncommon. There has not been shown to be any close relation, except of proximity. Functional disease, with disturbances of menses—a dysmenorrhea exists as a law of cause and effect. Four cases in hospital at the same time recently, unmarried women from 17 to 23 years, had had irregular, painful menses. In one of these cases where an anomaly existed of the appendix, passing for a short distance between the coats of the intestine, making a tight stricture, the menstruation had always been painful, and recently a local peritonitis had occurred at menstrual epoch. Our case records, other than these 4, show that these are not coincidences. A locked or torpid colon, with gas accumulations, an exaggeration of menstrual phenomena, increased pallor, or muddy complexion, languor, pains, nausea or vomiting, pronounced nervous irritability, peevishness with febrile rise to 98½° F. or 100¼° F., especially during the latter part of the day, if a tender, enlarged appendix is found, establishes the diagnosis. A recurrence of this group of symptoms at one or more succeeding menstruations may be expected. The thermometer showing a hovering of the temperature about the 99½° mark, has come to the clinical test. The tolerance of the female pelvis to disease should not mask the diagnosis, nor should a serious attack of appendicitis be permitted. Remove the appendix early; it will be a surprise to see its condition, and a gratification that it was done.

VIVISECTION AND ANTIVIVISECTION.

A Correspondence Between Mr. James M. Brown, President of the American Humane Association, and Professor William W. Keen, of Philadelphia.

THE following correspondence has been submitted to us by Dr. Keen. It speaks for itself without special introduction. Our comments will be found in the editorial columns.

LETTER FROM THE PRESIDENT OF THE AMERICAN HUMANE ASSOCIATION.

TOLEDO, O., October 4, 1900.

Prof. William W. Keen, Late President of the American Medical Association, Jefferson Medical College, Philadelphia.

DEAR SIR:—My attention has just been called to a passage in the published "Report of the Hearing" before the Senate Committee, held at Washington last February, on the Bill for Regulation of Vivisection. In this volume, the following conversation between Senator Gallinger and yourself is recorded.

Senator Gallinger. "What knowledge have you of the advances made by vivisectionists that have led them to progress from the brute creation to the human creation in making these so-called vivisection experiments?"

Dr. Keen. "I presume that you refer to a pamphlet issued by the American Humane Society. I have only to say in reference to it that there were a number of experiments which I would utterly condemn. Of the experiments narrated in that pamphlet, I have looked up every one that I could. Only two are alleged to have been done in America. Many of them are so vague and indefinite that I could not look them up, but as to those that I could, some are garbled and inaccurate—not all of them, observe."

Senator Gallinger. "Some of them?"

Dr. Keen. "Some of them."

A statement of this character, based upon such authority, it is impossible to ignore. Proceeding from one less eminent than yourself, in that profession which you represent and adorn, it might pass without notice; but coming from you, sir, such a charge must be investigated and probed to the fullest extent. Its importance is evident, and in testing its accuracy, you will give me, I trust, every assistance in your power.

First, regarding the cases of experimentation upon human beings recorded in our pamphlet, "Human Vivisection," you informed the Senate Committee that *many of them are so vague and indefinite that I could not look them up*.

We challenge the accuracy of that statement, and ask for proof. Of the various series of experiments upon human beings, made for the most part upon women and children in hospitals and infirmaries,—the authorities given in this pamphlet are as follows:

1. *Bulletin of the Johns Hopkins Hospital* for July, 1897.
2. *Boston Medical and Surgical Journal* for Aug. 6 and 13, 1896; *The Philadelphia Polyclinic* for Sept. 5, 1896.
3. *New York Medical Record* for Sept. 10, 1892.
4. *The British Medical Journal* for July 3, 1897; the *New England Medical Monthly* for March, 1898.
5. *The Medical Press* for December 5, 1888; the *British Medical Journal* for Aug. 29, 1891; the *London Times* for June 27, 1891, (and other journals).
6. *The Medical Brief* for June, 1899.
7. "Ringer's Therapeutics," pp. 585, 588, 590, 591, 498, 503; the *London Lancet* for Nov. 3, 1893.
8. *The Newcastle Daily Chronicle* for Sept. 21, 1888.
9. *The Medical Press and Circular* for March 29, 1899; the *London Lancet* for May 6, 1899, p. 1261.
10. *The Aug. Wiener med. Zeitung*, Nos. 50 and 51.
11. *Deutsche med. Wochenschrift*, Nos. 46 and 48 of year 1894.
12. *Deutsche med. Wochenschrift* of Feb. 19, 1891.
13. Lecture before Medical Society of Stockholm, Sweden, May 12, 1891.
14. *The British Medical Journal* for Oct. 15, 1881; *Medical Reports* for May 16, 1893; the *Nineteenth Century* for Dec., 1895.

For one series of experiments in the above list,—those made by Dr. Jansen upon children of the Foundlings' Home, (with the "kind permission" of the head physician, Prof. Medin) because, as he said, "calves were so expensive," it

appears that the only authority given was a reference to his lecture, delivered before a Swedish Medical Society upon a certain date. Although, so far as known, the facts there stated, have never been denied, yet the reference may, perhaps, be called indefinite. But one case is not "many." To what other of the references above given, did you refer when you informed the Senate Committee that "*Many of them are so vague and indefinite that I could not look them up*"? Had you stated that your library,—ample as it is,—did not contain, and could not be expected to contain all of the foreign authorities to which reference was made, there would have been nothing to criticize. I must assume, sir, that you have not put forth an aspersion of another's reliability merely to have acknowledgment of the inadequacy of your sources of reference; that the proofs of your statement, covering "many" cases, are available, and, in the interest of accuracy, I ask you to produce them.

Second. There is yet another point to which I ask your attention. You made the statement before the Senate Committee that in regard to our published account of cases of human vivisection, "*many of them are so vague and indefinite that I could not look them up; but, as to those that I could, some are garbled and inaccurate; not all of them, observe.*"

This, sir, is a most serious charge. You distinctly declared that of the cases personally investigated by yourself, as quoted in the pamphlet on "Human Vivisection," some are "garbled and inaccurate." We deny the charge, and again challenge production of evidence upon which it is made.

A "garbled" quotation is one which, by reason of omission and perversions, is essentially unfair. Sometimes it is a statement from which parts are omitted or transposed for the purpose of conveying a false impression. To omit quotation of parts, not directly bearing upon the question, for sake of brevity,—this is not "garbling," for all quotations would then be impossible. We assert that in quoting accounts of the cases of human vivisection, no omissions of essential facts have been made sufficient to impair the accuracy of fairness of the quotation. Let us put the matter to the test. Point out, if you can, the "some cases" which you found "garbled and inaccurate," and in proof of the charge, quote the omitted sentences or words, which, had they been inserted, would cause you and the general public to justify and approve the experiments on human beings, which we have so severely condemned.

Third. You stated, sir, before the Senate Committee, that only two experiments upon human beings "are alleged to have been done in America." I question, sir, whether that remark is quite in accord with the highest ideals of truth; it is the language of doubt; it seems to signify and imply that even you are aware of no other experiments upon human beings than two cases which are thus "alleged." I am very confident, sir, that you will not venture formally to assert—what you have seemed to imply—that you know of but two experiments upon human beings, made in this country, and recorded in the medical literature of the United States. There is, indeed, need of further enlightenment, if the medical profession of this country, so worthily represented by yourself, is ignorant of what has been done by men without pity and without conscience.

Trusting to have response from you at an early date, I am,
Yours most truly,

(Signed)

JAMES M. BROWN,
President.

REPLY OF DR. KEEN.

1729 CHESTNUT STREET, PHILADELPHIA, PA.,
January 21, 1901.

James M. Brown, Esq., President American Humane Association, Toledo, Ohio.

DEAR SIR:—Your letter of October fourth reached me promptly, but as I then notified you would be the case, very pressing engagements, absence, etc., prevented an earlier reply.

Now that I have a little leisure, I can answer your letter and furnish you in detail the proofs for which you ask.

There are two pamphlets, both entitled "Human Vivisection." First, one of 80 pages "printed for the American Humane Association, 1899," the other of 7 pages "published by the Humane Society, Washington, D. C.," without date, but from its contents, published a little later, as it is chiefly

a synopsis of the same instances reported more fully in the larger pamphlet. Hereafter when I speak of "the pamphlet," I mean the larger one unless I specifically mention the smaller one.

This larger pamphlet consists of two parts: first, (pp. 3-12) a reprint of a portion of "Senate Document No. 78" and the rest of it of various quotations, translations and comments. No name is attached to either part to indicate who is responsible for the accuracy of the references, the translations or the quotations. As the whole is preceded by an open letter signed by the president and secretary of the American Humane Association, and as you refer to the pamphlet as "ours," I presume the Association holds itself responsible for such accuracy, especially as you as its new President challenge me for proof.

The pamphlet purports to furnish a reprint of a portion of "Senate Document No. 78" and refers to this document in a way that would lead uninformed readers to suppose that this is a document expressing the sentiments of the United States Senate. It is, therefore, important to call your attention to the fact that Senate Document No. 78 is simply a collection of statements and papers by various persons printed by order of the Senate, but in no sense expressing the opinions or convictions of that body. The last paper in this document is one on "Human Vivisection," by "A. Tracy."

In two respects "A. Tracy" has a right to complain that the reprint is inaccurate. First, it omits to print the name of the author "A. Tracy." Surely he (or she?) should receive whatever credit there is attaching to his work.

Secondly, on page 30, line 8 of Senate Document No. 78, I read "A. Tracy's" comment. ["This patient, therefore, was scientifically murdered."] This statement the reprint very wisely omits—but there are no indications of the omission. Of this, more hereafter.

Your letter challenges the accuracy of my statements in three particulars.

1. I stated that many of the references in the pamphlet are "vague and indefinite."

2. I said that some of the accounts of the experiments are "garbled and inaccurate."

3. I stated that of the experiments narrated in the pamphlet only two were alleged to have been performed in America.

You will pardon me if I indignantly resent your imputation of untruthfulness in regard to this last statement. You entirely misinterpret my statement, which had no reference to my knowledge or ignorance of any other American experiments. I said that the pamphlet only contained two instances of such experiments which were alleged to have been done in America. These are recorded on pages 4 and 5 of the pamphlet. All the rest were done in Europe, South America, and Hawaii, years before it came into our possession. If you still question the accuracy of my statement and believe that there is a third instance of experiments done in America and described in the pamphlet, point it out by page and paragraph.

Turning now to the other two really important matters referred to in your letter, let me again state clearly the question at issue. It is not whether the experiments meet with my approval, but solely whether the reports of them in the pamphlet issued by the American Humane Association are reliable and accurate both as to their sources and their substance.

I. MANY OF THE REFERENCES ARE VAGUE AND INDEFINITE.

The references are so vague and indefinite in many cases that the statements and quotations made cannot be verified by consulting the originals. The preface of your president and secretary states that: "In each case the authority is given," and what sort of "authority" do you depend upon?

Newspaper medicine and surgery are notoriously inaccurate. I have personally had so much experience and observation of this that I am always certain that at least one-half or more of the statements in newspapers in reference to medical matters are inaccurate, not purposely, but only because the writers are not medical men. Yet you depend for the accuracy of your statements upon newspapers as follows. (I follow the inaccurate spelling of foreign names in your pamphlet):

1. The Vienna correspondent of the *London Morning Leader*, Jan. 26, 1899 (p. 3), of whom more hereafter.

2. The *Deutsche Volksblatt*, Jan. 25, 1899 (p. 3).
3. The Washington correspondent of the *Boston Transcript*, Sept. 24, 1897 (p. 9), of whom more hereafter.
4. The *New York Independent*, Dec. 12, 1895 (p. 11).
5. The *London Times*, June 27, 1891 (p. 16).
6. The *Tägliche Rundschau* of Berlin. (p. 17); no year, month, or day being given.
7. The *Vossische Zeitung* of Berlin, no year, month, or day being given (p. 18).
8. The *Vorwärts*, no year, month, or day being given (p. 18).
9. The *Danziger Zeitung*, July 23, 1891 (p. 18).
10. The *Schlesische Volkszeitung*, July 24, 1891 (p. 18).
11. The *Hamburger Nachrichten*, July, 1891, no date stated (p. 19).
12. A correspondent of the *Newcastle* (England?) *Daily Chronicle*, Sept. 21, 1888 (p. 22).
13. Dr. R. E. Dudgeon, in the *Abolitionist*, April 15, 1899 (p. 24).
14. A letter by Dr. Edward Berdoe to the *London Chronicle*, without year, month, or day (p. 29).

Few of these fourteen newspaper references can be consulted in this country; five of them (Nos. 6, 7, 8, 11, and 14) are impossible of consultation for want of any date whatever.

In no case would I be willing to admit a newspaper paragraph, a nonprofessional and usually unsigned statement (even if correctly quoted) as a sufficient authority for a grave charge against an individual or the profession.

Look for a moment what stuff Senator Gallinger stated at the "Hearing" he had himself caused to be printed. It is published on page 31 of the "Hearing" and on page 3 of the pamphlet. It consists of cable dispatches printed in some newspaper—Senator Gallinger did not even remember its name. The author of the dispatch from London is utterly unknown. The dispatch states that "the Vienna correspondent of the (London) *Morning Leader* says" so and so. Who and how reliable is the Vienna correspondent? He says that "the physicians in the free hospitals of Vienna" do so and so. Who are the physicians? In what hospitals were these deeds of darkness done?

And upon such evidence it is seriously proposed to indict the medical profession! Whether these dispatches are "garbled and inaccurate" in their alleged facts who can find out?

If a lawyer tried to convict a man of petty larceny on such testimony he would be laughed out of court. And yet a Senator of the United States and the American Humane Association actually adduce such statements as evidences of the gravest charges and spread them broadcast!

I now add six other "vague and indefinite" references not to newspapers.

15. On page 13 there is a quotation from Tertullian. The reference in the footnote is "Tertullian, *De Anima*, vol. ii, pp 430, 433, tran. by Holmes." I have compared the quotation with Clark's Edinburgh edition of the "Translation of Tertullian by Holmes," the date of the edition being 1870. No such quotation exists on pages 430, 433. Possibly it may be that the quotation is from another edition. No edition is named in the pamphlet; another instance of a "vague and indefinite" reference.

16. On page 17 a formal accusation is quoted as made by a Dr. Eugen Leidig against certain surgeons. No reference whatever to any book or journal is given by which the accuracy of the quotation can be tested. Is not this again "vague and indefinite?"

17. On page 24 is a reference to a paper by "Professor E. Finger, of Vienna (*Allg. Wiener med. Zeitung*, Nos 50 and 51)." No year is given, a somewhat essential part of the reference, as there are over forty volumes of this journal, each with the weekly numbers 50 and 51. No such paper by Finger is published in that Journal at least from 1890 to the present time. The reference is quoted from a paper by Dr. R. E. Dudgeon in the *Abolitionist* (an English journal) of April 15, 1899. I have been unable to consult this journal. If Dudgeon gave the year, then the Humane Association pamphlet has misquoted him. If he did not, then both the Association's pamphlet and he have been "vague and indefinite."

18. On page 25 again is a reference to a statement in a "lecture before the Medical Society of Stockholm," by Dr. Jansen of the Charity Hospital, reporting certain experiments. No reference whatever is given even to a newspaper much less to any medical journal. As the statement is in quotation marks, it purports to be the exact words used and ought to have had some source to which a reference was possible, especially as the preface of the pamphlet says "in each case the authority is given." I am glad to see that in your letter you recognize this as one in which the reference is really inadequate. I notice, however, that even in your letter you do not supply this missing reference. You say the facts asserted in the Jansen paragraph have never been denied. Of course not. The first requisite is to know whether they are correctly quoted.

Turning now from the larger pamphlet to the smaller one, which was spread broadcast by house to house distribution in Washington, at the time when the hearing on this matter took place last winter, I find repeated in this a number of the same vague and indefinite

references and garbled and inaccurate quotations already or to be described, to which are to be added the following:

19. On page 3 an extract from a report referring to experiments upon insane patients is printed in quotation marks. The only reference is to a "published report" in 1890 of the "Medical Staff of the Public Insane Asylum in Voralberg, Austria." The librarian of the Surgeon General's office informs me that there are two small insane asylums in the Voralberg, namely,—at Hall and Valduna. Some reports of the former are in the Library and in them no account of the experiments referred to can be found. No reply has been received to a letter addressed to this asylum as named in the pamphlet and written over a year ago.*

20. On the same page is an account of some experiments on bacteria from boils and the reference is to the *Deutsches Volksblatt*, no day, no month, no number, no page, nor even the year is given. If this is not "vague and indefinite," what is?

21. On page 24 there is an account of Kroenig's experiments (to which I shall recur later). No reference whatever is given to the source from which the account is taken.

II. SOME OF THE STATEMENTS ARE GARBLED AND INACCURATE.

To be vague and indefinite in charges affecting the morals and the reputation not only of individuals, but in fact of a whole profession is bad enough, but to make statements that are "garbled and inaccurate" is, as your letter recognizes, a much more serious matter. Let me consider the instances in detail.

1. "Vivisection Experiments upon the Insane," pages 4 and 5.

In the following quotation, the words of the original which I enclose in brackets are omitted. "To these patients the thyroid tablets [each pill representing 5 grains of the fresh sheep's gland] were administered," etc. This omission is of moment, because any one familiar with the administrations of thyroid extract knows that the doses used by Dr. Berkley are frequently given to human patients, including the insane, without producing symptoms dangerous to life, but on the contrary with benefit. I have myself given such tablets to patients with goiter for weeks together in larger doses than Dr. Berkley used.

In the following paragraph the quotation is garbled by omitting the words which I enclose in brackets: "Two patients became frenzied and of these one died before the excitement had subsided [the immediate cause of the exitus being an acute disseminated tuberculosis]." And again in the next paragraph, giving a report of the same case, the pamphlet quotes: "The thyroid extract was now discontinued, but the excitement kept up . . . for 7 weeks, at the end of which time she died." One would think this was the end of the sentence and that she died from the effects of the thyroid tablets. Not at all. The original continues as follows: she died "with the clinical evidences of acute miliary tuberculosis," (galloping consumption). Does this not come within the definition of garbling given in your letter? "A 'garbled' quotation is one which, by reason of omission and perversions, is essentially unfair."

To say that this patient, who actually died of galloping consumption died from the effects of the thyroid extract which had not been given for 7 weeks before death is as absurd as it would be to say she had died from the effects of moderate doses of laudanum given 7 weeks before. Yet "A. Tracy's" comment on this case is "[This patient, was, therefore, scientifically murdered]." Your Association mutilates its reprint by wisely omitting this piece of absurdity though the omission is not indicated. Moreover, the pamphlet states "there is no intimation that the administration of the poisonous substance was given for any beneficial purpose to the patients, for he took care to select patients that were probably incurable." On the contrary, Berkley's original paper expressly states that instead of being incurable, one (Case No. 1) was cured and another (No. 3) was improved. Besides this, though the pamphlet is dated 1899, it omits all reference to Dr. Berkley's letter to the *British Medical Journal* for October 30, 1897, in reply to your friend Dr. Berdoe, which shows that, as a result of the administration of the thyroid tablets to these 8 patients—a well-recognized remedy for insanity†—

not one died from the effects of the drug, but that on the contrary, two of those alleged "incurables" were cured—25%!

In his admirable letter to *Life* (December 6, 1900), Dr. Berkley says: "The purpose for which the article was written was to show to the medical profession that a certain medicament in common use was not free from objection, and should not be given in unsuitable cases. In proper ones the results are among the most resplendent attained by modern medicine, converting the drooling dwarf into an intelligent, well-grown man or woman; or, in other instances, as in myxedematous insanity, affording the otherwise hopelessly insane with almost a specific to recover their reason."

2. The Cases of Lumbar Puncture by Dr. Wentworth, of Boston (p. 5).

"Lumbar Puncture," I may remind you, is the simple insertion of a hypodermatic needle between the vertebrae into the sheath of the spinal cord, but below the cord itself, to obtain a few drops of the cerebrospinal fluid for diagnosis.

The pamphlet gives what is called a "brief abstract" of five of the experiments related. The abstracts are indeed brief, so brief as to give a wholly erroneous impression as to the causes of the patients' death. The omissions are glaring instances of what the logicians call a *suppressio veri*, equivalent to a *suggestio falsi*. Let me point this out in detail.

Case 2.—It is correctly quoted that the last puncture (where there were several punctures I only give the last date) was made "February 16, on day of patient's death." The pamphlet fails to add, however, the important fact stated by Dr. Wentworth that the postmortem showed an empyema [abscess in the chest] which had burst into the lung, pneumonia, and inflammation of the brain with pus as the cause of death.

Case 3.—The pamphlet correctly says, "Puncture January 17, 1896; patient died January 22." What Dr. Wentworth adds is omitted, namely, "No symptoms attended or followed the operation." Moreover, the postmortem showed that the patient died from the widespread changes common to infantile wasting.

Case 5.—The pamphlet says, "Puncture February 3, 1896; patient died February 4." It omits to state what immediately afterward follows, that the postmortem showed "primary tuberculosis of the intestines. Double pneumonia," as the cause of death.

Case 6.—The pamphlet quotes, "Punctured February 1; patient died in convulsions three weeks later." It neglects to state what Dr. Wentworth particularly mentions, "No reaction on the part of the patient attended the operation," and it also fails to state that the child was seen only once and that the diagnosis then made was tubercular meningitis, which was clearly the cause of the child's death, three weeks later.

Case 7.—The pamphlet quotes, "Punctured February 27; patient died February 28." It omits the fact that the postmortem showed that the child died from defective development of the brain and other causes; and that the history showed that the child, who was 7 months of age, had "frequent convulsions, which began when he was about 3 months old. While in the hospital the convulsions occurred not less than 20 times a day. Oftentimes he had several in an hour."

The inference from the pamphlet's "brief abstracts" of these cases is clearly, and it seems to me by these omissions was meant to be, that the deaths were due to the lumbar punctures, whereas the evidence is that the deaths were due to other causes, and in two instances the operation is expressly stated not to have done any harm. Are not these abstracts "garbled and inaccurate"?

3. On page 7 the pamphlet refers to some experiments on the inoculation of lepers with syphilis, made in Hawaii, but published in the *New York Medical Record* of September 10, 1892. It is stated that the patients "were already suffering from one incurable disease and the object of the experiment was to ascertain whether with another, and even worse disorder, they might not be infected." This statement is incorrect. Most writers recognize only three stages of syphilis, primary, secondary, and tertiary. The writer of the article in question believed that leprosy was a fourth and final stage of syphilis and not an independent disease. It is a well-recognized fact by all scientific writers that a patient suffering from syphilis in any stage is immune to an inoculation of the virus; that is to say, the inoculation will not "take" if

* This letter was written by myself and not by the librarian of the Surgeon General's office.

† I quote the following from the eighth edition of Hare's "Therapeutics" as to the use of thyroid extract: "In the dose of from 5 to 20 grains (0.35 to 1.3) three times a day [i.e., 15 to 60 grains a day] according to the degree to which it produces its effects, it has proved of value in acute mania and melancholia, puerperal and climacteric insanities, and in stuporous states with primary dementia." Berkley's maximum dose was 15 grains a day.

he is already a syphilitic. It was for the purpose of determining whether leprosy was a fourth stage of syphilis that the attempt was made. None of those inoculated took the disease.

4. Sanarelli's Experiments on the Inoculation of Yellow Fever, page 8.

The references here are to the *British Medical Journal* for July 3, 1897, and the *New England Medical Monthly*, March, 1898. The extracts marked with quotation marks are from the *New England Medical Monthly*. Between the first and the second sentences of the quotation there should be some stars to note an omission, but none such appear. The omitted words state that *not* the germs of the disease, but the carefully filtered and sterilized germ-free fluid was used. Besides this and many other minor inaccuracies many of the scientific terms are changed into non-medical terms, which is not objectionable in itself. But such changes and inaccuracies should exclude quotation marks, for when used they mean that the words quoted are the *ipsissima verba* of the author, if in the same language, or an exact translation if from a foreign language.

But this is the least of all. The pamphlet says that the injection produced certain symptoms, among which are mentioned "the jaundice, the delirium, *the final collapse*," the last three words being in italics in the pamphlet to call special attention to them. In the *British Medical Journal* and in the *New England Medical Monthly*, the words "the final" are *not to be found*. We see not a few patients suffering from "jaundice, delirium, and collapse" who recover, but when the expression is changed to "the final" collapse, it means to everyone that the patient died.

Moreover, the end of the quotation is as follows: "I have seen [the symptoms of yellow fever] unrolled before my eyes thanks to the potent influence of the yellow fever poison made in my laboratory." *This entire sentence does not occur* either in the *British Medical Journal* or in the *New England Medical Monthly*. Whether it is quoted from some other source not indicated, or has been deliberately added, I leave you or "A. Tracy" to explain.

Moreover, immediately afterward on the authority of the Washington correspondent of the *Boston Transcript* it is stated "it is understood that some if not all of the persons inoculated died of the disease" and then seven times afterward are repeated "the final collapse," the "unrolling before the eyes," "scientific assassination," "death" and "murder" quoted from a public speech before the American Humane Association. Let us see if these *were* "murders."

In the two references given there is no indication whether any of these patients died or not. How, therefore, "it is understood that some, if not all of them died," I do not know. As a matter of fact none of the human beings inoculated by Sanarelli died, as anyone desirous of learning the truth could have ascertained by consulting Sanarelli's original publication reporting his experiments with full details. (*Annali d'Igiene Sperimentale*, 1897, vol. vii, Fascic. iii, pp. 345 and 433.)

What hysterical oratory about "the final collapse," which was not final; "scientific assassination," which did not assassinate; and "murder" of those who were so disobliging as still to live! And this on the authority of the Washington correspondent of the *Boston Transcript* who, the pamphlet assures us, is a person "who would seem to be unusually well informed in matters of science!" An excellent example of "newspaper medicine" and a good reason for my refusal to accept it as evidence, especially from other correspondents who may not be as "unusually well informed." May I ask whether "the Vienna correspondent of the *London Morning Leader*" is also one of those who in your opinion is "unusually well informed in matters of science" and whether his testimony is as wholly false as the one under consideration?

5. On page 23, the pamphlet quotes an account of some experiments by Dr. Neisser from the *Medical Press and Circular* (England) of March 29, 1899." This is an instance again of misquotation and omission which can scarcely be other than intentional. The last sentence of the first quotation states: "Of these 8 girls, 4 developed syphilis." No stars indicate that any words have been omitted. The original reads: "Of these 8 girls, [5 were prostitutes, and of these 5] 4 developed syphilis." The words in brackets are entirely omitted in the pamphlet. They make a deal of dif-

ference, for what is more probable than that 4 out of 5 prostitutes should develop syphilis? Whether it makes any difference or not, however, is at present not the question. The issue is whether the quotation is "garbled and inaccurate." Does it not fulfil another of the definitions of "garbling" given in your letter, viz., "omissions of essential facts . . . sufficient to impair the accuracy or fairness of the quotation?"

Moreover, the pamphlet's comment upon this case is as follows: "Does the London journal which reports these awful experiments denounce them as a crime against every law of morality? Not at all. It simply says that 'it would be difficult to acquit Dr. Neisser of a large measure of responsibility in respect of the causation of syphilis in these cases!'" Could reproof be more gentle?

Is that really all that the *Medical Press and Circular* "simply says"? On turning to that journal after the above sentence, which is correctly quoted, the editorial continues thus: "We, however, are less concerned in establishing the culpability of Dr. Neisser than in condemning the spirit which prompted such experiments. All measures, even if novel, which may reasonably be expected to assist in bringing about the recovery of the patient without injury to his health may legitimately be resorted to with the consent of the patient, but measures, whether by drugs or by operation, which have not for direct object the cure of the patient and which may prove inimical to his health or condition, are inadmissible under any circumstances and must expose the perpetrator to professional ostracism and to penal rebuke."

Is "professional ostracism and penal rebuke" a reproof than which nothing could be "more gentle"? If this statement is not "garbled and inaccurate," what do words mean? How could this misrepresentation be otherwise than intentional?

6. On page 24, again, reference is made to the experiments of Menge.* The extracts being in quotations marks would purport to be exact translations. This is not the case. The collocation of the paragraphs, also (especially in the smaller pamphlet), is such that it would be supposed even by a careful reader that the babies experimented upon were inoculated with the germs taken "from the pus in the abdominal cavity of a person who had died of peritonitis," without any precautions or preliminary experiments, and that, therefore, these babies were exposed to a fatal infection. This is not true. Four columns of text in the original intervene between the first and the second paragraphs alleged to be quoted, and these detail experiments which proved that the inoculations which he then carried out would almost certainly be harmless. The result showed that he was right, for not the slightest ill-effects followed. I have only words of condemnation for Menge's experiments, but to misrepresent these experiments is scarcely less culpable than to perform them.

7. Then follows a brief account of Kroenig's experiments. The object of these the pamphlet says were "to observe the surest way of breeding purulent bacteria." This is not true. On the contrary, his object, like Menge's, was to determine how these bacteria are normally *destroyed* in the part of the body in which the experiments were made. In only a single instance did any ill effects follow, and in this case the inflammation was brief and not dangerous either to life or health. In fact, the very titles of these two papers proclaim the destruction of the bacteria and not the surest way of breeding them, as Menge's title reads, "On a quality (Verhalten) of the vaginal secretion in non-pregnant females, which is hostile to bacteria," and Kroenig's is on the same peculiarity in pregnant women.

In the comment on these two series of experiments, they are spoken of as inoculations "with loathsome diseases," which would suggest to any one that the patients were successfully inoculated with syphilis or other similar diseases. This was not the case. Only inflammation would follow even had the inoculations been successful.

Moreover, to show the vague looseness of the alleged quotations, the two paragraphs on the experiments of Menge are in quotation marks and are introduced by the words "He says: 'the bacteria I used, etc.,'" as if they were exact continuous translations. "He says" nothing of the kind. Instead of being exact translations, the first paragraph is made up of partly correct and partly incorrect translations

* *Deutsche medicinische Wochenschrift*, 1894, Nos. 46 to 48.

from page 891 near the top of the second column and near its middle; and the second paragraph of partly correct and partly incorrect translations from page 907 near the bottom of the first column.

No reference whatever is given to Kroenig's paper either by number, date, or page. Is not this "vague and indefinite"? As a matter of fact it is the same journal (No. 43, p. 819) as Menge's paper, but published three weeks earlier.

8. On page 25 is one of the most outrageous instances of garbling and mistranslation, or worse, which I have ever known to be perpetrated even in antivivisectionist publications. It relates to observations and experiments of Professor Schreiber, reported in the *Deutsche medicinische Wochenschrift* of February 19, 1891.

The subject is introduced with the startling caption: "Inoculations with Tuberculin and Germs of Consumption." In the smaller pamphlet the caption is simply: "Injected Germs of Consumption." What was injected was not the "germs of consumption" at all, but tuberculin, a substance which at the date of Professor Schreiber's publication was engaging the attention of physicians throughout the civilized world as a therapeutic and diagnostic agent. To describe inoculations with tuberculin as "inoculations with the germs of consumption" can be attributed only either to gross ignorance or to wilful disregard of the truth.

In the first paragraph occurs the sentence: "He began with one decimilligram and continued to inject the tuberculin in ever-increasing quantities, until he at last injected as much as 5 centigrams, about 50 times as much as Koch said was the maximum dose for children of 3 to 5 years old." Any fair presentation of these experiments would have included Professor Schreiber's sentence which he prints in bold-faced type: "But even with so large a dose injected at one time, the children showed *no trace of a reaction.*" It would, perhaps, be too much to expect your society to have indicated on what grounds Professor Schreiber was led to the employment of such large doses, and that his observations demonstrated for young infants an exceptional tolerance of tuberculin, a phenomenon for which there are analogies with other drugs.

But the worse falsification is the succeeding account, in the form of what purports to be an exact translation of Schreiber's inoculation of a boy with tuberculin. The alleged quotation begins: "I am sorry to say that it is very difficult to obtain subjects for such experiments. There are, of course, plenty of healthy children in consumptive families, but the parents are not always willing to give them up." The words "I am sorry to say that," and the entire next sentence "There are, of course, plenty of healthy children," etc. are *not in the original, but are additions made out of the whole cloth.* The next following sentences contain many inaccuracies, such as the translation of the German words "beträchtlich angeschwollen" as "swelled up enormously," instead of "swelled up considerably." But the worst is the deliberate insertion of the following sentence italicized in the pamphlet which also does not occur in the original: "I cannot yet say whether the boy will be consumptive in consequence of my treatment." The correct translation of Schreiber's words at the point where this closing sentence appears in the pamphlet is as follows: "I could discover no other alterations in the otherwise apparently healthy boy." [Andere Veränderungen konnte ich an dem sonst gesund scheinenden Knaben nicht entdecken.]"

While I have said enough about this case to substantiate my charge of garbling and inaccuracy, I cannot refrain from utilizing it also to show the utter misapprehension which the citation of detached sentences and paragraphs from medical articles is calculated to create in the mind of a non-medical reader. Even when the words are quoted correctly, they are likely, when detached from the context, to give rise to entirely false impressions. This is a criticism which applies not only to other examples cited in this pamphlet, but to a very large number of reports of experiments and of quotations from medical journals and books current in antivivisectionist writings, and the resulting dissemination of erroneous conceptions is often greater even than that caused by inaccurate or garbled quotations. A brief explanation of the present example will show the justification of this charge.

For what purpose did Professor Schreiber inoculate the boy with tuberculin? His article leaves no doubt as to the

answer. He points out the importance of the earliest possible recognition of tuberculosis in a patient in order to secure the best curative results. The boy's mother had consumption, and the author calls attention to the frequency of unrecognized tuberculosis in the offspring of tuberculous parents. The boy received a small dose (1 milligram) of tuberculin, which, if he were free from tuberculosis, would produce no effect, but which if he had unsuspected tuberculosis would produce a transient (though possibly a severe) fever and a local reaction, indicative of tuberculosis. Such a reaction followed the injection of tuberculin, and the diagnosis of tuberculosis, which had not been, and very likely could not have been made in any other way, was established. I do not know what could have been more fortunate for this boy than the recognition in its incipency of a disease previously unsuspected, and which, recognized thus early, should in all probability be cured by proper treatment. This tuberculin test is constantly employed to prevent the spread of tuberculosis in our cattle. In our children it enables us to discover the same disease in an early, curable stage. Shall we care for our cattle better than for our children?

Its use is not properly to be called an "experiment" at all. As I write this, I find in the *Journal of the American Medical Association* for January 12, 1901, page 75, 3 cases of the use of tuberculin in human beings by Prof. J. M. Anders, who points out its value in enabling us to diagnosticate consumption "in latent forms and dubious cases however incipient" long before percussion or the stethoscope will reveal the disease. I can imagine his surprise if he were charged with making 3 horribly cruel "experiments" and injecting the "germs of consumption."

It is euphemism to call such an alleged quotation, in which words and one entire sentence are interpolated and another wholly changed in meaning, a "mistranslation" or even a "garbled and inaccurate" account. Does it not amount to literary forgery? It is another illustration of the fact that when an antivivisectionist attempts to say anything about scientific experiments either the moral sense is blunted or the truth-telling faculty is in abeyance. A good English example is the misstatements in Miss Frances Power Cobbe's book laid bare by Victor Horsley, and Schreiber's and Sanarelli's cases will serve as excellent examples of American misrepresentation—if so long a word is needed to describe them.

I am sorry my reply is so long, but in fewer words I could not explain the many and gross errors to be pointed out. I have given you indeed "many" instances in which the references are "vague and indefinite" and "some" in which the accounts are "garbled and inaccurate." These adjectives are, I submit, very mild ones to apply to such a pamphlet.

You can hardly be surprised after the extraordinary and repeated interpolations, mistranslations and worse which I have demonstrated in this letter that I am unwilling to accept any alleged quotation or translation emanating from the American Humane Association as accurate and truthful unless I can compare it with the source from which it is derived.

In conclusion let me commend to the "Humane" Association the closing words of President Elliott's letter to be found on pages 218-9 of the "Hearing."

"Any attempt to interfere with the necessary processes of medical investigation is in my judgment in the highest degree inexpedient and is fundamentally inhuman."

I shall take the liberty of publishing my reply. I suppose that you will not object to the publication of your letter with it in order to explain the reason for the reply?

Very respectfully yours,

WILLIAM W. KEEN.

Jenner Institute of Preventive Medicine.—The following appointments have recently been made at this institution: Dr. S. G. Hedin, of the University of Lund, Sweden, has been appointed Head of the Department of Pathological Chemistry; Mr. J. Beresford Leathes, Lecturer on Physiology at St. Thomas's Hospital Medical School, assistant in the same department; and W. J. Young, of Owens College, Manchester, assistant in the Chemical Department. Drs. Moore, Petrie, and Mackenzie have been elected to fill the three Research Studentships.

1.—In discussing gastric ulcer, Robson excludes from his remarks ulcers due to tubercle, syphilis, and malignant disease. Ulcers are divided into "erosions" and "simple ulcers." The latter is subdivided into the acute round ulcer, most frequently found in young women and frequently complicated by hemorrhage and perforation, and the chronic irregular ulcer more frequently seen in men, but, according to Robson, not infrequently found in the female sex. Symptoms and diagnosis: Pain after eating, with vomiting and tenderness in the epigastrium, are the most indicative symptoms of ulcer. In many cases no symptom of the condition is present until there occurs a sudden hemorrhage or perforation. The kind of pain will often indicate the seat of the disease. For instance, an ulcer on the posterior wall will give rise to more pain when the patient is recumbent, and an ulcer on the anterior wall will be most painful when the patient is prone. When the ulcer is at the pylorus the patient is more comfortable when on the left side, and the reverse is true if the ulcer is at the cardia. When the ulcer is situated in the anterior of the wall of the stomach there is greater tenderness over the epigastrium. Vomiting is apt to give marked relief from pain in cases of ulcer, but this is not true of cancer of the stomach. The presence of hydrochloric acid in excess favors the diagnosis of ulcer. The blood in the vomit is apt to be free or clotted, though it occasionally resembles the coffee-ground vomit of cancer. Distention of the stomach by the evolution of carbonic acid gas will show whether or not dilatation is present. In chronic ulcer of the stomach a tumor may not infrequently be felt. The duration of the chronic ulcer, which is usually of years, as compared with the short duration of cancer, will frequently aid in a differential diagnosis. When there is doubt as to the diagnosis, an exploratory abdominal section may be made if the following two questions can be answered in the affirmative: First. Can an exploratory operation be performed without adding seriously to the risk of loss of life? Second. Is it possible that good will result from the exploration? Treatment should be medical, but if the ulcer becomes chronic, does not respond to treatment, or complications arise, surgical treatment is the only one which will give relief. Robson thinks that the medical treatment should be kept up for a much longer period than is usual, in order to prevent relapse.

Surgical treatment. Robson's mortality in operations for gastric ulcer is below 5%, and he thinks this mortality could be lowered if many of the cases were operated upon earlier. When medically treated the mortality rate is from 20% to 50%. Gastroenterostomy is the operation which Robson thinks most universally applicable to these cases, and he always attaches the bowel to the posterior surface of the stomach. His last 20 cases have all recovered without complication. Excision of the ulcer is not always necessary. **Pyloroplasty** can be done for pyloric ulcer if the pylorus is free from extensive adhesion, can be easily drawn forward, and is not actively ulcerated. If these conditions are not present, gastroenterostomy is to be preferred. Pylorotomy is seldom necessary for simple ulceration. Dilatation after the method of Loreta is not a satisfactory procedure. **Compli-**

cations. Perforation occurs in about 15% of all cases of ulcer of the stomach. That death does not occur in all cases of perforation is due to the fact that the stomach is usually empty and that the omentum becomes adherent at the point of perforation. Protecting adhesions, however, are rare and cannot be depended upon. Perforation not infrequently results in the formation of a subphrenic abscess. **Hemorrhage** occurs in about 80% of cases of gastric ulcer. Robson thinks that in acute hematemesis the treatment should be medical, but that in recurring acute as well as chronic hemorrhage surgical treatment should be instituted. **Cicatricial contraction of the pylorus** resulting in dilatation of the stomach is not an infrequent complication of gastric ulcer, and occasionally gastroplication is necessary as well as direct treatment of the stenosis. Robson has operated upon 11 cases of hour-glass contraction of the stomach as a result of ulcer. Perigastritis with adhesions frequently results from ulcerations of the pyloric end of the stomach, producing dilatation and requiring surgical interference for its relief. [J.H.G.]

2.—Barker describes the case of a woman, aged 42 years, who had suffered since the age of 14 with more or less gastric disturbance and vomiting. Six years before admission the diagnosis of gastric ulcer was made. For the past 16 months the patient had used a stomach tube daily. On admission the patient was extremely weak and anemic, and the stomach was largely dilated, a diagnosis was made of nonmalignant pyloric stenosis. As preparatory treatment for operation, the stomach was frequently washed out, and on the two days preceding the operation saline solution was injected subcutaneously. A posterior gastroenterostomy was performed in the usual way, but before closing the intestinal opening liquid food was thrown into the bowel. The pylorus was bound down by adhesions and was nearly completely closed. The patient recovered promptly from her operation and gained rapidly in flesh and health. [J.H.G.]

3.—Cousins reports a case of **retroperitoneal cyst** which he incised and drained successfully. He does not think that enucleation of these cysts can often be accomplished, and that the undertaking is accompanied by considerable danger to life. Where the pedicle is small, however, he thinks enucleation should be done. [J.H.G.]

4.—Robinson reports a case of **strangulated femoral hernia** in which he performed a resection of the bowel by the Maunsell method. The patient made a good recovery. [J.H.G.]

5.—Anderson, speaking of the mortality following operations for the **radical cure of hernia**, shows the percent to be about one in 100, in nonstrangulated cases. Out of 190 operations, including cases of strangulation, he had 4 deaths, 2 of which occurred in strangulated cases. He thinks that the Halsted-Bassini operation is the best method of obtaining a radical cure. He believes that with this operation, patients can be assured of a radical cure. Unless the cord is large, he does not resect the veins, and thinks this should never be done in children. He uses silk as his suturing material, and has had no cause to regret its use. In 60 operations done in the past year, in which silk was used, he has not had infection to take place in a single case, nor has he ever seen late infection follow the use of silk sutures. He does not advise the use of a truss after the operation, as it does no good, and is apt to do damage. In children he thinks the radical cure should be undertaken if the ring is large, and the hernia is not successfully controlled by the truss. [J.H.G.]

1.—Dickinson delivered a lecture on **Considerations touching the pathology and relations of diabetes**, at the St. George's Hospital. He emphasizes that from the clinical standpoint the disease is well defined, but that from the pathological aspect much is still to be learned. He states that an uncommon form of diabetes is associated with lesions of the pancreas and a more common variety, with a good lead of certainty, is associated with diseases of the nervous system. He mentions as the most common pathological change, blood extravasation into the perivascular canals of the brain, particularly about the deeper arteries. He states that he has preparations showing these hemorrhages in 8 out of 22 diabetic brains. He also refers to syringomyelia which occurred twice in 8 diabetic spinal cords, and in 3 spinal cords there was hyaline modification of the lateral parts of the gray horns. Attention is directed to the important fact that the nervous system rapidly undergoes changes after death, also that the saccharine blood may have an influence upon the nerve structures, therefore confusion as to origin and effect necessarily arises. The diabetic liver is described as being enlarged, congested, red and firm. He refers to pulmonary consumption in relation to diabetes with particular mention of a form not of tuberculous origin. The inflamed kidney and other changes of the genito-urinary tract are probably due to the passage of saccharine urine, and that diabetic cataract is presumably due to the saccharine blood. The hemorrhages in the brain, previously described, are probably in some way associated with the cause of the disease, and not due to the saccharine blood. Reference is made to the discovery of Claude Bernard, and to Baron Larrey's case of diabetes (in 1820) in a man of 22 years of age who developed diabetes after an extensive wound of the brain made by the thrust of a foil. He states that reference might be made to many cases of head injuries which are followed by glycosuria, most often of a temporary nature. Grief, terror, anxiety, and commercial disasters are frequently followed by diabetes. Diabetes, as reported by Mr. Herbert Page, surgeon to the London and Northwestern R. R. Company, is twice as common in the engine-driver as in the ordinary population. The close association of gout and diabetes and the hereditary tendency of the disease are set forth. The occurrence of loss of patellar reflex in a large proportion of the cases and peripheral neuritis as clinical manifestations of the nervous system are mentioned. He also states that the appearance of earthy phosphates in the urine of diabetics shows the relation of the disease to cerebral irritation. The redness of the mucous membranes of the mouth, particularly of the tongue, and the dusky redness of the face also suggest involvement of the nervous system. He refers to glycosuria as being a concomitant of some cases of insanity, and that while the pathology of both remains largely a problem for the future, there are indications of cerebral changes, and the association between the two conditions seems conclusive. The address is concluded by mentioning that the important clinical observations of this disease are the following: Mental causes acting as an origin; the association of excessive phosphaturia; absence of patellar reflex; and the relation of glycosuria and insanity. [F. J. K.]

2.—In his lecture on **femoral hernia**, Battle discusses at some length the diagnosis of the condition, and lays great stress upon a thorough examination for hernia in all cases of intestinal obstruction. He recalls two instances where he had been called in to operate for intestinal obstruction, when in each case femoral hernia was present and had been overlooked. Patients should be examined standing as well as in the recumbent position. A varix of the internal saphenous vein is sometimes mistaken for femoral hernia, as are also enlarged glands and lipomata in the femoral region. A careful examination of the femoral ring will, in most instances, suffice to differentiate these conditions. When a

femoral hernia is irreducible, it should be operated upon, unless some condition exists which is a positive contraindication. In speaking of the radical cure of these cases, Battle thinks it is a mistake to adhere to one method of operating, and that it is better to change the technic to suit the individual case. He then describes a method which he has employed on three occasions, which consists in the implantation of a portion of the aponeurosis of the external oblique muscle into the femoral ring. This has been followed in each case with very satisfactory result. [J. H. G.]

3.—Nicholls and Learmonth discuss the **hemorrhagic diathesis in typhoid fever and its relationship to purpuric conditions in general**. The authors report a case of hemorrhagic enteric fever. They mention that this term should be used in referring to such cases of enteric fever that show purpuric eruptions of the skin, bleeding from the mucous membrane such as hemoptysis, hematemesis, metrorrhagia and epistaxis. Degeneration of the walls of the bloodvessels are mentioned as factors which are produced by circulating toxin. They state that 4 cases of hemorrhagic typhoid fever have occurred in a series of 200 cases at the Royal Victoria Hospital, Montreal. The case reported by the authors is that of a female of 21, unmarried, and a school teacher by occupation. She was admitted to the Royal Victoria Hospital on June 19, 1900, giving a history of feeling ill for 6 days. A chill, followed by fever, marked the onset of the disease. After a short time the diagnosis of enteric fever was made, rose spots appeared, the tongue was dry and coated, and the Widal reaction was positive. The spleen, however, was not enlarged. Fourteen days after admission a purpuric eruption showed itself upon the skin of the abdomen. These hemorrhages in a few days began to fade. Some days later extensive hemorrhages showed themselves. The patient had 2 hemorrhages from the bowels, there were epistaxis, bleeding from the lips and gums, hematuria and hemorrhages into the conjunctivae. A blood examination at this time showed that there were 13,000 leukocytes. At a later time the blood-count showed 1,540,000 erythrocytes and 35% of hemoglobin. Death occurred on the third of July. The treatment consisted of 18 cold baths, these were stopped when the hemorrhages appeared. Bleeding from the mucous surfaces was treated with supranal powder, and spirit of turpentine and liquor calcei chloridi were administered internally. The case is interesting on account of the sudden onset and absence of splenic enlargement. A postmortem examination made 2 hours after death revealed typhoidal ulceration involving principally the large intestine, but the small bowel was also implicated. Hemorrhages were found in the skin, lungs, heart, kidneys, spleen, intestines, bladder, gallbladder, and connective tissues. There was an old healed duodenal ulcer, acute diffused nephritis was present, the spleen was small and there were some old pleural adhesions. Microscopical examinations revealed fatty degeneration of the capillaries of the lungs and kidneys. The most important fact in reference to the pathological findings is the fatty degeneration of the endothelial cells of the capillaries in the lungs and kidneys, but the authors emphasize that rupture of the capillaries could not be demonstrated. A bacteriological examination was made, cultures being taken from the blood in the heart, peritoneal cavity, and kidneys. The bacillus typhosus was not demonstrated, but the staphylococcus albus was isolated from the blood in the heart and peritoneal cavity as well as from the kidneys. From the blood in the heart a bacillus was also isolated; the characteristics of this organism were the following: The bacillus showed bipolar staining properties; it had rounded ends and was four times as long as it was broad. It was nonmotile, gave an acid reaction in litmus milk and also produced coagulation, formed gas in glucose broth, and was nonpathogenic when inoculated into rabbits. A bacillus was isolated from the kidney, which was regarded as being identical with the bacillus fluorescens liquefaciens. The authors have tabulated statistics from various sources to show the infrequency of hemorrhagic typhoid fever. The total number of cases collected were 12,000, and in this number there were only 18 cases which showed the general hemorrhagic diathesis. They next refer to the etiology of this condition, pointing out as an important fact that scorbutic, hemophilic, or rheumatic taint does not seem to have been noted in the cases. In reviewing the pathology they state that the lesions differ little from those encountered in ordinary typhoid fever. The hem-

orrhages into the tissues and from the free surfaces show considerable diversity as to character and distribution. From the information that can be gathered the bacterial origin of this hemorrhagic condition is probable, but that final proof is still lacking. From the standpoint of onset and symptoms they state that the condition usually occurs in well-developed cases of enteric fever, and that the purpuric manifestations are most frequent in the third week of the disease. This fact strongly suggests that secondary infection acts as the most important cause. They regard the prognosis as very grave, two-thirds of the cases ending fatally. The treatment which is recommended is purely symptomatic, stating that with the appearance of the hemorrhagic state, the cold-bath treatment should be stopped. They mention the treatment recommended by Gerhard, who includes vegetable juices in the diet. They also refer to the many plans of treatment adopted to check the hemorrhage. The authors conclude the article by giving a classification of purpuric conditions. [F.J.K.]

4.—Smith in discussing the treatment of **typhoid fever** lays particular stress upon the examination of the stools, and that the appetite of the patient must be carefully watched. In the management of enteric fever he states that he has laid down a golden rule to examine the stools at least once in 24 hours. The appearance of undigested milk or other food in the stools has led the author to diminish the quantity of food or suspend feeding for 24 hours. The appearance of blood in the stools he states is an indication for the use of opium and the stopping of all food for 24 or 48 hours. When sloughs make their appearance in the stools, which is a natural state during the third or fourth week of every case, hemorrhage may be feared, so that feeding should be cautious. Feculent debris is a desirable constituent of the stools and should indicate the persistence in the line of treatment which has been adopted. He believes that the appetite of the patient indicates the character and amount of the diet, and he has made it a cardinal rule to allow the patient to be the sole arbiter of his diet, the only contrary indications to feeding being vomiting, hemorrhage and tympanites. He advises feeding 4 times during the 24 hours. Sleep, however, is more valuable than feeding, therefore the patient should never be aroused to be fed. He recommends the following articles in the dietary: Liquid custard, baked custard pudding, junket, bread and milk, eggs lightly boiled or poached, jelly and soups, beef tea, beef juice, and stale bread. He does not deny the patient beer or stout. In the treatment of complications he states that vomiting should be controlled by withholding the food, and by the administration of hydrocyanic acid, bicarbonate of soda and bismuth. When tympanites occurs he advises the withholding of all food, the administration of sulphate of soda until the bowels are acting freely. He also recommends that an ice-bag should be placed upon the abdomen. Constipation is treated by the routine administration of calomel. As a rule he does not fear excessive diarrhea, but when undigested particles of food appear in the stools food should be stopped for a while. For the fever he recommends tepid sponging and for hemorrhage from the bowels starvation and the administration of opium. He advises as a routine treatment the administration of either carbolic acid or chlorine water, and in some cases salol. Alcohol he believes should not form a necessary article for the treatment of this disease. He concludes the article by saying that with this method of treatment he believes his results as regard mortality are as good as those with any other plan of treatment and maintains that convalescence is more rapid; relapses, however, are not prevented. [F.J.K.]

5.—Filatow's spots in morbilli are discussed by Falkener. He states that Filatow described them in 1895 and Koplik in 1896, and that they have usually been called Koplik's spots. Koplik described them as bluish white, but the author states that these spots appear as fine white specks. They are easily removed by rubbing. After these spots have persisted for a short while they are surrounded by a red areola. The buccal mucous membrane is the commonest site for Filatow's spots, appearing opposite to the lower molars or upper molars on either side. They are also found upon the inner surface of the lower lip and upon the inner surface of the upper lip. He lays stress upon the fact that in every one of his cases Filatow's spots were observed. From the standpoint of differential diagnosis they are sometimes

to be distinguished from permanent spots upon the mucous membrane, also from curds of milk which collect upon the mucosa, from thrush and aphthous stomatitis. The author has never noted the absence of Filatow's spots in measles, and he has never observed them in any other condition, having examined the mucous membrane of the mouth in from 3,000 to 4,000 cases. They are of great importance from the standpoint of diagnosis, for when they appear the case is most certainly one of morbilli. From the standpoint of early treatment and isolation this sign is of great value. [F.J.K.]

6.—Davis reports a case of **tuberculous peritonitis** in which abdominal section and toilet of the peritoneum resulted in considerable improvement. He thinks it a mistake not to operate in these cases early when there is a chance of obtaining beneficial results. [J.H.G.]

7.—Tunncliffe and Rosenheim in an article conclude that after an investigation relating to the recent beer-poisoning epidemic that selenium compounds would explain many anomalous cases in which the dose of arsenic was very small, and feel justified in stating that these compounds have played an important role with the arsenic. [F.J.K.]

9.—Whipham relates a case of **primary carcinoma of the vermiform appendix** not diagnosed during life but found postmortem. The peritoneum was studied with carcinomatous masses, and one ovary also was the seat of malignant disease. The mucous membrane of the appendix was seen to be extensively involved by spheroidal-celled carcinoma; the muscular coat was only slightly involved. This was the only portion of the alimentary canal that was the seat of malignant disease and Whipham thinks this argues for its being the primary seat. The cancerous condition of the left ovary he considers to be due to dissemination. Microscopic sections of the appendix are shown and other reported cases referred to. [J.H.G.]

New York Medical Journal.

1. Stethophonometry. ALBERT ABRAMS.
2. Septicemia in Young Chickens. LEO F. RETTGER.
3. A New Portable and Inexpensive Ophthalmometer. WILLIAM F. AIKEN.
4. Combined Surgical Operations in Female Subjects at a Single Seance. R. STANSBURY SUTTON.
5. The Normal Declinations of the Retinal Meridians. GEORGE T. STEVENS.
6. A Study of Buboos and Their Treatment. FREDERICK GRIFFITH.
7. Hysterical Anesthesia and Analgesia. B. C. LOVELAND.

1.—Albert Abrams, in an article on **stethophonometry**, remarks that **auscultation** of the heart-tone in the conventional manner not infrequently affords us no indication of cardiac strength, if reliance is to be placed on the intensity of the tones in their selective propagation to different parts of the chest. Abrams has devised an instrument which he calls the **stethophonometer**. This instrument is constructed on the disc-valve principle, weighs only two ounces, and is composed wholly of hard rubber. He believes that the employment of this instrument will add greater scientific value to our clinical examinations, in recording the intensity of the acoustic phenomena associated with the heart and lungs. [T.L.O.]

3.—After considering the principles of some of the ophthalmometers used at present, Aiken describes a **new portable and inexpensive ophthalmometer** devised by him. The author claims that the instrument has proved reliable for measuring the corneal convexity. The principle is that of doubling a square image in the direction of one diagonal, the opposite corners touching; the opposite sides of the square thus serve as mires. In the absence of astigmatism, a perfect cross is formed; when astigmatism is present there is a faulty alignment of one pair of sides with a correct alignment of the other pair at right angles. No counting of "steps" is required as a scale of the draw-tube indicates each axis when the arms of the cross in the corresponding meridian are in line. The spherometric range of the instrument is from a curvature $r=5.5$ millimetres to $r=13$ millimeters. The

instrument can be employed with a patient in the position of ophthalmoscopy thus enabling the examiner to determine the astigmatism and make the ophthalmoscopic examination with the patient in the same position. The article is comprehensively illustrated. The instrument is detachable and easily portable. [N.R.D.]

4.—Sutton, of Pittsburg, remarks that until a very recent period when a female patient required 4 or 5 distinct surgical procedures, many months were frequently required for her recovery. Edebohls, of New York, has encouraged the practice of operating at one time upon the several lesions without regard to their number. Sutton reports 15 cases in which several operations were done at one time and uneventful recovery followed. [T.L.C.]

7.—Loveland, reports a case of **hysterical anesthesia** and analgesia in an unmarried woman of 24 years. This case is reported as one of **hysteria major**. The sensation was normal in the head and neck anteriorly and posteriorly. There was tactile, thermic and pain analgesia from the collarbone to just above the nipples in front, and over an equal area in the back, both shoulders and arms being included in anesthetic area. On the front of the body the sensation was normal from the nipples down, along the line of the body to the tenth rib, where an area of extreme **hyperesthesia** began and extended to the groins. On the back normal sensation extended from the lower angles of the scapula to the gluteal folds, except at two small points just below the scapula which were extremely sensitive. In other words they were **hysterogenic zones**. Electrical stimulation of these spots immediately developed an hysterical attack. The limbs, including the feet, were devoid of all sensation. A deep puncture with a large needle produced no evidence of feeling. The upper limit of this condition being the groin in front and the gluteal fold in the back. Contrary to what is usual in such cases, puncture with a surgical needle was followed by some **blood ecchymosis**, though the skin presented the usual pale appearance. The line between the sensitive and insensitive areas was sharply defined. [T.L.C.]

Medical Record,

1. The Problem of Appendicitis from the Medical and Surgical Points of View. ROBERT ABBE.
2. The Causes of Failure of Compensation in Diseases of the Heart. MORRIS MANGES.
2. Strabismus and its Management. J. H. WOODWARD.

1.—Robert Abbe discusses the problem of **appendicitis from the medical and surgical points of view**. He presents for careful study a number of specimens selected from several hundred and arranged in groups of 10 to illustrate important points of difference. These specimens present respectively single strictures, multiple strictures, those in which **concretions** have formed, another in which a partial sealing of the canal had occurred with, however, a remnant of the canal remaining, to produce further trouble. One or 2 cases of the series are interesting in illustrating the fact that even a completely obliterated cavity may leave an atrophied appendix which is the seat of a painful neuralgia requiring its removal. One series shows a small follicular ulcer. The idea embodied in the word **catarrhal appendicitis** is a correct one in the very early stages in the morbid condition. Excluding the rarer cases when foreign bodies are entrapped, or in which the **kinking of the appendix** from its short mesentery, the **origin of the stricture** is found in 1 of 2 causes, **septic and linear ulcer** or the **contraction of the catarrhal inflammation**, antedating this stricture by many years. From this study it may be said with certainty that the first attack of appendicitis recognized by the patient is in most cases the end of the disease, for the appendix shows the presence of a stricture which may have existed for many years. The most complete experience clinically of the variations in the symptoms is often required to differentiate between the disease in question and so unlike a malady as typhoid fever. The latter study of leukocytosis throws much light upon the differential diagnosis. Abbe concludes that attacks may often be cured by natural methods; that a long

respite does not mean a cure, and that it is impossible to predict a cure; and finally, that unless the appendix is removed, the disease is always latent where once it is begun. [T.L.C.]

2.—Morris Manges discusses the **causes of failure of compensation in diseases of the heart**. He prefaces his article with a resumé of the opinions of authorities on this subject, and clinically groups the causes of the condition as follows: (1) Failure of general nutrition of the body; (2) disturbance of local nutrition of the heart; (3) increased work of the heart; (4) functional cardiac disorder; (5) effects of improper treatment. These causes are discussed under their respective captions. [T.L.C.]

4. Treatment of Lupus. H. ROCKWELL VARNEY.
5. A Report of Some Cases of Abdominal Surgery, with Remarks on the Diagnosis of Carcinoma of the Cecum and the Surgical Treatment of Carcinoma of the Liver and Gallbladder. CHARLES GREENE CUMSTON.

1.—Jacobson reports a very interesting case of a young girl, 11 years of age from whose **stomach** he removed a large **hair-cast**. For about two years prior to the operation the patient had suffered from considerable gastric disturbance and pain. Frequent vomiting was also present. About a year before the operation, a cucumber-shaped swelling was noticed in the upper part of the abdomen. The attacks of pain became so frequent that the patient lived largely on milk. She appeared much younger than she was, was thin, ill-nourished and quite nervous. Nothing abnormal was found about the abdominal viscera, but a large, hard, slightly nodular tumor could be palpated above the umbilicus. In shape it was somewhat like a kidney and freely movable. No definite diagnosis was made. The abdomen was opened and the tumor was found to be within the stomach which was opened and a large hair-cast was removed. Both wounds were closed. The patient recovered from the operation and admitted that during all her life she had bitten off and swallowed her hair. At first she did this because she was nervous, but later because she rather liked the tickling sensation produced by the hair in its transit to the stomach. The tumor was 6 inches long, had much the shape of the stomach, was about 2½ inches thick and about 2½ inches in breadth. It weighed 15 ounces. The pyloric end extended into the stomach. Full-sized photographs of the mass accompany the article. Jacobson referred to the frequency of this condition in animals, particularly in the cow, and then discusses 19 cases which have been reported as occurring in human beings. In several instances intestinal obstruction followed the presence of a hair ball, with perforation and death. None of the patients were insane, but a number were described as hysterical. The stomach in a number of instances tolerated the foreign body without rebellion. In one case the mass of hair weighed 5 pounds and 8 ounces. In one case there were two masses of hair found in the stomach. Of the 19 reported cases 10 were discovered post-mortem and 9 upon the operating table. In no case was a diagnosis made. Because of the movability and shape of the tumor it has often been mistaken for a movable kidney. Jacobson finds in one other case the regular recurrence of pain at night from which his own patient suffered. In nearly every case it was not discovered that the patient was a hair eater until after the foreign mass had been removed. In most of the fatal cases death resulted from perforative peritonitis. There was not a single death in the 9 cases operated upon. [J.H.G.]

2.—H. A. Hare mentions the frequency with which **scurvy** in infancy is mistaken for **acute articular rheumatism** and mentions as a point of differential diagnosis the rarity of articular rheumatism in the first 5 years of life. A frank case of scurvy is easy of recognition, but many atypical cases are found. He describes 8 cases, the first in

which the child cried bitterly every time it was moved, particularly if the movement involved the change in the position of his back. An orthopedic surgeon believed that spinal disease was present, and a line of mechanical treatment was followed. No benefit was observed, but after a time scurvy was diagnosed, and under proper treatment, cure followed. His second case also presented similar symptoms of spinal trouble, but careful examination of the child revealed the fact that its gums were slightly spongy, and no evidence of disease in its spine, joints, or head could be demonstrated, the diagnosis of probably scurvy was made, and cure rapidly followed the treatment instituted. The third case was that of a child who suffered at the end of its first year with almost complete paraplegia. It was plump, but pallid, and its gums and mouth presented the characteristic scorbutic symptoms. This child had been fed upon the best cow's milk with the addition of well known form of artificial infant food, and scurvy had not been considered possible. However, under the proper dietetic regimen a speedy cure followed with total disappearance of all the paralytic symptoms. Hare points out that scorbutus in infancy is a disease of the children of the well-to-do, in distinction from rickets which on the other hand seems to be the disease of the poor. [T.L.C.]

3.—Guerard discusses the relation of tuberculosis to the tenement-house problem. He emphasizes the deleterious effects of poor ventilation, lack of sunlight and the effects of overcrowding. He points out the repeatedly observed fact that in many instances tuberculosis occurs again and again in the same house. He has carefully studied the maps and records of the New York City Board of Health, in the Fourth and Sixth Wards of the City and he found that 38% of the total number of dwellings had cases, including deaths, of consumption reported from them during the years 1894, 1895 and 1896. Of these cases one-half occurred in 23% of the affected houses, this being but 9% of all the dwellings in the wards. One-fourth of the houses had apparently become permanently infected as shown by a repetition of three or more cases in them in the three years. In some houses as many as eight cases occurred. During a period of eight years previous to 1897, 136 cases were reported in 12 houses, and he estimates that 200 or more cases of consumption, or an average of about twenty per house, had occurred in these twelve houses in the eight years. These particular wards were studied on account of the dense population and poor surroundings. He believes that much can be done by enforcing landlords to observe the following requirements: 1 To make ample and suitable water closet provision for the number of persons to occupy the house. 2. To supply each set of apartments with a separate water supply and bath. 3. To provide separate storage for coal. 4. To provide sufficient means for washing clothes. 5 To provide pantry accommodation for the keeping of food. The city itself can do much to ameliorate the condition of its poor by establishing public baths and wash-houses as well as providing public squares and breathing spaces. The infected houses should be razed and building laws more stringently enforced. In a table appended to this article it appears that the deaths from phthisis constitute about one eighth the deaths in New York City, and about 91% of these cases occur between the ages of 16 and 65. [T.L.C.]

4.—Varney discusses the treatment of lupus by the x-ray. In passing the x ray through the spectroscopé one sees at the chemical end of the spectrum a combination of 2 of the primary colors, red and blue or ultra violet. He believes that it is by the action of the strong chemical colors that the stimulating influence on the tissues is produced. This is the same principle as that devised by Finsen in which he uses the ultraviolet rays of white light. The results are about the same except the x-ray is somewhat more rapid in its action with shorter exposures, and larger areas may be treated at a sitting. The treatment of lupus by the x ray is painless, its exposures are of short duration, and the area treated may be of any size or location. There is no scar from the treatment if the exposure is properly conducted. The time of exposure is regulated by the density of the rays and the results are evident with much less scarred tissue. [T.L.C.]

5.—The next case reported by Cumston was one of carcinoma of the cecum complicated by appendicitis. The patient was a woman, 48 years of age, who suffered from attacks of appendicitis, for the relief of which a diseased and

adherent appendix was removed. The operation, however, did not relieve the patient's suffering, but the symptoms increased with loss of flesh and symptoms of obstruction of the bowels. A second operation was done, an annular carcinoma of the colon was found, but the patient's condition was not such as to stand a resection and an anastomosis and hence an artificial anus was formed. The patient died a few hours later. The symptoms of carcinoma are summarized as pain, alternating diarrhea and constipation, loss of flesh, dyspeptic disturbances, and intestinal hemorrhage. Physical signs are absent, of course, at the onset of the disease, but later a movable tumor can be palpated which finally becomes fixed. Edema of the leg may follow from compression of the iliac vein. The next case is one of carcinoma of the gallbladder with secondary deposits in the liver, which followed within a year an operation for the removal of gallstones, which was entirely satisfactory. In this case Cumston removed the gallbladder and a large portion of the liver. About two years after the operation, the patient showed symptoms of extensive malignant disease of the liver. Cumston thinks that extirpation of the gallbladder is justifiable only in the presence of malignant disease or of severe inflammatory lesions. [J.H.G.]

10. Anastomosis of the Ureters with the Intestine. A Historical and Experimental Research. REUBEN PETERSON.

1.—Reynolds discusses the major obstetrical operations from the standpoint of the general practitioner. The operations to be considered in all of these cases of pelvic contraction are forceps, version, induction of premature labor, craniotomy, the cesarean section with or without extirpation of the uterus, and symphysiotomy. The choice between these must always be determined by a consideration of their respective maternal and fetal mortality, under the conditions of the individual case. The conclusions to which he has been forced by his study of the subject are as follows:

1. When the conditions are such that the child can be delivered with anything like reasonable ease by forceps or version; one of these operations is preferable to any cutting operation. 2. When the mechanical relations would render forceps or version unusually difficult, forcible, and prolonged; and when the mother is in the favorable class, the equally low maternal mortality and the far lower fetal mortality of the cesarean section render it the operation of choice. 3. When the mechanical conditions make the intrapelvic delivery of an intact child at term impossible, or unduly difficult, the great superiority of the cesarean section over the induction of premature labor in fetal mortality, and its extremely low maternal mortality, render it again the preferable operation. 4. When the ordinary operations fail and the woman is in the unfavorable class, symphysiotomy is the operation of choice, and may be expected to lead to a favorable result for both mother and child in the great majority of cases, provided always that the degree of mechanical difficulty permits of its application. 5. When, in the unfavorable class of cases, the degree of relative disproportion between head and pelvis is too great to admit of a safe symphysiotomy, craniotomy to the living child should be unhesitatingly chosen, since the maternal mortality of either form of the section is so enormous, and because the life of the potential mother of many children is of more value than that of any unborn fetus. [W.A.N.D.]

2.—In his paper on the treatment of sessile and other ovarian cysts, Stehman gives the clinical results of a method which he claims is simple, applicable in a certain percentage of these cases, and, so far as he knows, not usually employed. Then nonpedicular cysts of the female adnexa as a rule develop either from the ovary—paroophoron—or the parovarium; for the most part they grow between the layers of the broad ligaments, and thus are in intimate relation with the cellular tissue, vessels, ureter, and bladder beneath and in front; the muscular and serous coats of the broad ligaments and ovary on the sides; and the superimposed tube and peritoneum above. His method includes the following steps: After carefully walling off the intestines, the cyst is aspirated and about three-fourths of the collapsed wall removed; the interior of the remainder is thoroughly painted with tincture of iodine and, by the aid of a long dissecting forceps and needle-holder, the marginal ends are turned in with an over-and-over continuous stitch. The abdominal wound is then sutured and sealed. He claims that recovery after this operation is ideal. [W.A.N.D.]

3.—Eshner in an article on **paralysis agitans** reports 2 cases in whom the tremor was the least conspicuous of the symptoms. In the 2 cases the tremor was almost wholly absent and at times was very inconspicuous. In concluding the article he states that this disease may be unattended by tremor. [F.J.K.]

4.—Hughes advocates the **ambulatory treatment of fractures** of the thigh and leg and of certain cases of coxalgia and illustrates his article with cuts of an apparatus which he has devised and found useful in these cases. [J.H.G.]

5.—White, in discussing the possibilities of **liquid air to the physician**, tells of the manifold uses of this new therapeutic agent. In the treatment of abscesses the author believes that liquid air is to be preferred to any other form of local anesthesia. He also recommends it in the treatment of carbuncles, in the treatment of lupus and as a stimulant for chronic ulcers. The cauterizing effect is especially to be applied in the treatment of early epithelioma of the lip and even in some cases of nonoperative epithelioma cure may follow its application. [F.J.K.]

6.—In an article on **movement of intestines** by Bernheim the following interesting case is reported: An enema of cottonseed oil was administered to a woman suffering from floating kidney, nervousness and general debility. Five hours after the injection the patient vomited the oil. He gives an account of the work performed in this line by various investigators. The experiments of Bernheim show that antiperistaltic motions of the intestine may be produced by the injection into the large bowel of certain substances. He concludes by saying that nutritive enemata and the injection of medicine by rectum may be practised with good results. [F.J.K.]

7.—Considered editorially.

8.—Wheatley, in an article on the **metric system**,

gives his reasons why this system should be of general use in medicine and pharmacy. [F.J.K.]

9.—**Evolutional and involutional types** of mental and nervous disease are discussed by Mayer. He described at some length the different epochs of life as being of importance in the production of nervous instability. He considers the influence of childhood from many points of view. Then he passes to the influences of the age prior to puberty, the period of puberty, that of the adult, and finally considers the changes dependent upon the senile. [F.J.K.]

10.—To be treated editorially in the next issue of the JOURNAL.

Journal of Nervous and Mental Diseases.

January, 1901. [Vol. xxviii, No. 1.]

1. Diffuse Degeneration of the Spinal Cord. JAMES J. PUTNAM and E. W. TAYLOR.
2. Report of a Case of Brain Injury, with Peculiar Whistling Spells Following Operation. WILLIAM C. KRAUS.
3. Brush Massage. FRANK R. FRY.

1.—Putnam and Taylor present Bastianelli's classification, making two groups of degenerative spinal lesions in connection either with pernicious anemia or with the more chronic forms of malnutrition, between which the line of separation is not to be too sharply drawn. In the first group it is the anemia which dominates; the spinal lesions make themselves felt only towards the end of life, when they develop with great rapidity. In the second group, in which the more chronic cases belong, including most of those reported by various authors, the disease is one of the nervous system, the malnutrition being of secondary importance. Disease of the central nervous system, in cases of the second group, occasionally strikes beyond the limits of the spinal cord, involving the optic nerves. The anatomical lesions differ somewhat in character. In cases of the first group, according to Bastianelli, they are relatively slight and scattered, and the lateral columns in particular are relatively little affected, while in the second group they are more pronounced and the lateral columns more sharply and extensively involved. Bastianelli also found that lesions of the bloodvessels are less marked in the typical, quasisystematic, whole column degenerations. Putnam and Taylor do not altogether agree with Bastianelli, saying that his observations are not fully maintained by theirs, and that they do not find it to be invariably true that in the more chronic cases in which the nervous symptoms have played an important part for many years, the spinal lesions are necessarily most marked. [T.M.T.]

2.—Kraus reports the case of a man 27 years old, a herdsman in a stockyard, who some time previous to the accident, had a stroke of apoplexy, resulting in hemiplegia of the left side of the body with partial recovery. He was struck by a train, receiving three scalp wounds, one 2 inches long over the occiput, one 2½ inches long over the left parietal eminence, and another 2 inches long over the left frontal region. In addition, he sustained a depressed fracture of the skull, 3 inches above and 1 inch behind the left ear. After trephining and removing the depressed bone during the night the patient began to whistle as he had been accustomed to do when driving cattle, continuing for 1 minute and ceasing for 5 to 10 minutes, keeping it up at regular intervals until he died, 4 days after the accident. There was complete loss of control over bladder and rectum; no increase in temperature, and pulse slightly lowered. [T.M.T.]

3.—Fry recommends the use of brush massage in preference to the ordinary massage, and says that in this method the brush is kept in contact with the skin and manipulated with a combined circumlatory and creeping movement, with varying degree of rapidity and pressure. It adheres to the skin, drawing with it the superficial structure in a way that can hardly be described. Amplitude of the different movement depends much on the length of bristles and spring of the brush. The combined or special movement almost imparts itself to the hand of the operator or can be easily acquired. One of the advantages of this massage is that you can obtain operators, and even people of moderate means can avail themselves of the trial. It is also effective in the heaviest work for which massage is used. [T.M.T.]

Berliner klinische Wochenschrift.

3. A Grave Spinal Symptom-Complex Caused by a Serpentine Aneurysmal Change in the Spinal Bloodvessels. E. BRASCH.
4. On the Simplification of the Phenylhydrazin-Test for Sugar. A. NEUMANN.

1.—Two patients who had been given thallium acetate for the night sweats of phthisis developed areas of **alopecia**. This lead the author to make some experimental investigations with this drug. He found that feeding white mice with thallium acetate, alopecia could be produced, but only by a constitutional effect, as local application of the drug did not produce the same results. [M.R.D.]

2.—In experimenting upon guineapigs, Friedberger found that in a guineapig whose blood-serum caused the erythrocytes of the pigeon to agglutinate and then dissolve, that the urine of the animal also possessed that power. Also in a rabbit that had been immunized against pigeon blood, the urine showed this property, but naturally to a less degree than the blood of the animal. The experiments are still in process, but so far it appears that the substances of the blood causing the agglutination also enter the urine. [M.R.D.]

3.—The author's patient presented a clinical symptom-complex which was strongly suggestive of tabes. Microscopic examination showed dilatation and tortuosity of the arteries in a portion of the spinal cord together with hypertrophy of the vessel walls. The cord itself in the lower dorsal and lumbar regions was the seat of chronic degeneration, and also in the higher portions of the cord especially in the posterior and lateral tracts, as well as in the anterior cornua. Together with these changes the author at the postmortem examination found a cardiac hypertrophy with a coexisting contracted kidney. The chronic rise in arterial pressure seemed to be etiologically responsible for the thickening in the walls of the vessels, thus influencing the nutrition of the spinal cord. In addition to these spinal lesions secondary lesions were also found, and were recognized as marked ascending degeneration of the columns of Goll. [M.R.D.]

3. The Cardiorenal Theory. OTTO GROSS.
4. Cod-Liver Oil with Phosphorus. ZWEIFEL.
5. Reply to Dr. Knapp's "Aseptic Bougie." LEOPOLD SCHERBEK.

1.—Schmidt gives a detailed description of the **Boas-Kaufmann bacilli**, long, thread-like microorganisms, so often found in stomachs in which carcinoma exists, with a review of the literature. Then his own experiments follow. When blood was added to cultures of this bacillus, its growth rapidly increased. That it is rarely found in the stomach

contents, in benign conditions, may be due to the absence of blood in the stomach. The various causes which seem to favor its occurrence, are stagnation of the stomach contents; absence or decrease in the production of hydrochloric acid; absence of fermentation; erosion of the upper surface of the stomach; the presence of albumin-detritus and blood, following ulceration. He reports a case, a laborer, aged 37 years, who had had stomach symptoms over 8 years. He had attacks of pain, often lasting days, generally more frequent in the winter. The pain was near the pylorus, and worse at night, and he could not lie on the right side while it lasted. With constipation the attacks grew worse; after vomiting or lavage, they improved. This was undoubtedly a case of benign stenosis of the pylorus, probably due to a cicatrizing ulcer. The cultures from the stomach showed pseudo-lactic acid bacilli and other flora. Then he reports a case of a man of 63, who suffered from stomach trouble for 13 years, accompanied with much flatulence. From the stomach contents a pure culture of the bacterium coli grew, but no lactic acid or Boas Kaufmann bacilli. The case was one of carcinoma ventriculi. The colon bacilli, he explains, may have come from the oral secretion, following their ingestion with food or drink; or they might have come from the duodenum. [M.O.]

2.—First he explains that "Lasegue's sign" in sciatica is the fact that the affected thigh can be flexed at the hip without pain, when the lower leg is flexed at the same time; but when the lower leg is kept straight, flexion of the thigh at the hip causes intense pain. After reviewing the literature of the subject, he says that this phenomenon is due to the stretching of the sciatic nerve. Fajersztajn has noted that besides, a crossed phenomenon exists in most cases of sciatica; when the well leg is raised, with the lower leg straight, pain is felt in the sciatic nerve of the other side, near its exit in the buttock. He explains this theoretically, by supposing that stretching the well nerve causes pain in the affected nerve. He details experiments upon the cadaver to prove this. He found this new sign in 25 out of 41 cases, doubtful in 5 others. All were rheumatic sciatica. [M.O.]

3.—Gross compares the Epstein-Schwalbe work with Norden's, and finds that they disagree, the former advocating the ingestion of much liquid in **cardiorenal affections**, the latter restricting the liquid relatively to the amount of heart weakness. Lavage is thus a two-edged sword, increasing elimination, but overtaxing the heart-muscle. He advises lavage only when the heart muscle is not badly affected. [M.O.]

4.—Zweifel, whose feelings seem much hurt by the unjust criticism of Kassowitz, whose **cod-liver oil with phosphorus**, as Zweifel showed, contained very little, if any, metallic phosphorus, reiterates his opinion, with quotations from his earlier work. He states his arguments very clearly to prove that the cod-liver oil alone acts, when this preparation is given in rachitis, the phosphorus soon becoming phosphoric acid. [M.O.]

5.—Scherbek describes an **aseptic bougie** made by him very like that which Dr. Knapp described. But he thinks that neither Knapp's nor his bougie can be perfectly sterilized. [M.O.]

The New Osiris Pavilion in the Salpêtrière Hospital.—Marcel Baudouin (*Gazette Médicale de Paris*, January 19, 1901) says that this new building, erected through the munificence of M. Osiris, the Paris banker, cost over \$22,000. It is designed especially for gynecology, and Dr. Paul Segond will be its chief. It stands alone, opposite the chapel, with a garden in front of it. Down stairs are 5 single rooms for patients, a ward with 6 beds, and office for the superintendent, etc., and the operating room, with an anesthetizing room, a room for sterilizers and instruments, a small room adjoining for electrical apparatus, and a dark room. The **operating room** is large, well lighted, with a chain to divide the operator from the students. Bath-room and water-closets are at the extreme other end of the building, beyond the ward. Many of the furnishings are American, the steel bed-springs, the model of the operating table, etc. Dr. Segond, to whom the credit of finally obtaining this pavilion is due, will soon begin his course in operative gynecology. [M.O.]

THE VALUE OF SPUTUM-EXAMINATIONS TO THE
GENERAL PRACTITIONER.¹

By M. HOWARD FUSSELL, M.D.,

of Philadelphia.

Instructor in Clinical Medicine, University of Pennsylvania.

IN 1887 I had the honor of presenting before this society, a paper upon the Diagnostic Value of Tubercle in the Sputum.

In the period which has since elapsed the propriety of examining the sputum in cases of lung disease, not only for tubercle-bacilli but for other organisms, has been recognized by all writers.

The methods of examination, the improvement of the technic and the introduction into general use of oil-immersion lenses have made the detection of the various organisms a matter easily performed by any one at all skilled in the use of the microscope.

The demonstration of the methods of examination is now a part of the curriculum of every good medical school.

It might then be considered a gratuitous act to write a paper upon the value of this procedure.

But notwithstanding the fact that all careful diagnosticians recognize that in many instances an accurate diagnosis of lung tuberculosis cannot be made without a microscopic examination of the sputum, and while a routine examination of the expectoration is made in all well-regulated hospitals, I am convinced that anything approaching a routine sputum-examination by the general practitioner is not practised. Indeed I think that the sputum is not examined at all by the general practitioner except in rare instances.

It is with the idea of bringing the necessity of sputum-examinations before the family doctor that this paper was prepared. These thoughts present themselves to the writer on this subject:

First. The necessity of sputum-examinations.

Second. The value of sputum-examinations.

Third. The technic.

Fourth. The practicability of the procedure.

The necessity of sputum-examinations can best be presented, it seems to the writer, by quoting a number of cases in which a diagnosis was entirely impossible without the light shed upon the case by the examination of the sputum.

During the past two months three cases have presented themselves in the private practice of the writer in which the examination of the sputum made an otherwise doubtful examination positive in two and helped much in the third case.

CASE 1.—Mrs. H., aged 42 years, mother of four children. Family history was excellent, there being no case of tuberculosis or other hereditary disease in the family. The lady was of extremely nervous temperament and first came under my care two years ago while suffering with an attack of hysterical dyspnea. She was anemic, having about 70% of hemoglobin with a slight diminution in the number of red blood-cells. She was emaciated, afraid to venture outdoors for fear she would die of heart-disease. In a word, a typical neurasthenic, who unfortunately a year previously had been told by her doctor she had a weak heart. This fact worried her and she was unable to dispossess her mind of the fear of sudden death. Careful examinations of her heart, lungs, abdomen and urine, revealed only a rapidly-acting heart

without organic lesion. Her lungs showed no sign of disease. Under a carefully regulated life, with abundance of outdoor living, driving, walking, etc., which she willingly took when assured she would not die, she rapidly improved, gained 15 pounds in weight, and seemed entirely well one year ago. In August, 1900, I was again called to see the patient. She was suffering from exactly the same symptoms as previously, plus a very slight cough, with expectoration of perhaps half an ounce of sputum in the morning. There was no fever, as evidenced by careful thermometry. Examination showed the heart normal as before, with a very slight impairment of resonance at the apex of the right lung. Sputum-examination showed myriads of tubercle-bacilli, which have persisted ever since and which were present in the sputum yesterday. My previous knowledge of the extreme hysterical condition of my patient, together with the very slight physical signs, made me quite certain that I was dealing again simply with neurasthenia. The presence of tubercle-bacilli in the sputum, was practically the only way in which I was enabled to make a correct diagnosis.

CASE 2.—A young man of 22 consulted me during the recent epidemic of la grippe. His father and one sister died of phthisis several years ago. The patient had always been well until about 6 months ago, when he had a slight cough in the morning. He consulted a quack contract doctor in the city and for 6 months had been dosed with medicine at \$5.00 per month, paid in advance. Examination and questioning revealed that except for the morning cough the patient had been perfectly well until one week before my visit. He then had coryza, sore throat, aching limbs and a fever, probably an acute attack of la grippe. On examination he had a temperature of 100°. His throat was somewhat red and inflamed. In the region of the left nipple there was a distinct pleural friction with a slightly marked dull note on percussion. I made a diagnosis of influenza with some pleurisy, believing that consumption, which had been so glibly diagnosed by my brother at so much per month, was not present. Examination of the sputum at first revealed no tubercle-bacilli. A second examination showed an abundance of the organism in one slide and none in another taken from another portion of the same sputum. Here a diagnosis was surely and certainly made by the sputum-examination.

CASE 3.—L. C., male, 16 years of age, a large boy weighing 133 pounds, was seized in the beginning of November with one of the most virulent attacks of pneumonia it has been my lot to see in a boy of his age. A chill occurred at 10 A.M. By 4 P.M. he was semi-conscious, had a pulse of 130 and a temperature of 104°. Consolidation of the right lower lobe of the lungs rapidly developed. Pneumococci were abundant in the rather scant sputum. A blood count showed 22,000 white cells to the cm. of blood. After 9 days of desperate illness, a crisis occurred, for a few days the temperature remained about 99½° in the morning to 100° in the evening. Soon the fever took on a septic type, normal or nearly so in the morning, rising to 102° to 104° in the evening. A gradual rise in the number of leukocytes occurred. Constant, almost daily, examinations of the sputum failed to show tubercle-bacilli. Examination of the exudate from the lung procured by puncture also failed to show the organism. Frequent punctures of the chest-wall by a long needle failed to show pus. The physical signs denoted the absence of pus free in the chest, and failed to demonstrate a collection in the lung or between the lobes. However, on the strength of the increasing leukocytes, together with the absence of tubercle-bacilli in the sputum, confirmed us in a diagnosis of intrapulmonary or interlobular abscess. An operation was urged, but refused. In 9 weeks after the beginning of the illness, a diagnosis of intrapulmonary collection of pus was confirmed by the expectoration on three occasions of 8 ounces of pus. This pus showed the presence of streptococci and pneumococci, but no tubercle-bacilli. The patient is now entirely well. Here the negative findings in the sputum-examinations went a great way against a diagnosis of tuberculosis which seemed extremely likely.

Such cases as these might be multiplied many times, but these alone will suffice to make my point of the necessity of the sputum-examination in making a diagnosis which at the time would have been impossible by other practicable means. The value of this pro-

¹ Read before the Philadelphia County Medical Society, February 13, 1901.

cedure is demonstrated by the above cases in making the diagnosis. And it may be stated as a fact to which there are no exceptions, that the presence of tubercle-bacilli in the sputum indicates tuberculosis in the patient. The absence of tubercle-bacilli in sputum does not unfortunately always mean the absence of tuberculosis, but when repeated examinations, carefully made, do not show tubercle-bacilli, it is a valuable point against tuberculosis in the patient.

Sputum-examinations are of value in making an early diagnosis. Myriads of cases are yearly overlooked in the early stages of tuberculosis, because of the dearth of physical signs, which would be easily marked as tuberculosis if the trouble had been taken to make a sputum examination.

The value of an early diagnosis in tuberculosis being made is, beside the object of this paper, but one of its values. The possibility of destruction of sputa containing tubercle-bacilli as a prophylactic measure is beyond computation. A detection of these organisms in the early stages—only a month or a year earlier than a diagnosis would otherwise be made—would be of incalculable value to the human race.

This fact alone, it seems to me, must appeal to every practising physician. It is the family doctor who first sees the case. If he would make or have made an examination of the sputum in every case of continued expectoration, and have the sputum containing tubercle-bacilli destroyed, in a few years the cases of tuberculosis in the world would be greatly lessened. Instead of this trouble the patient is told all sorts of tales, until continued failing health, a progress of the physical signs, so that he who runs may read, at last suggests a sputum-examination, when the organisms are found. Can anyone calculate the new cases which will originate from such a neglected case, or the value in saving human life, by the expenditure of a few minutes of the doctor's busy life?

From the nature of things it is the detection of cases of tuberculosis in which sputum-examinations are of the greatest value. Besides, the detection of various parasites in the sputum is also of value. Recently Stiles, of the Bureau of Agriculture, read a thoughtful paper upon parasitic hemoptysis, which shows the necessity and value of sputum-examinations in many of the tropical regions.

As to the practicability of this procedure in the busy, rushing life of the general practitioner.

In cities such as Philadelphia and New York, which have a bacteriological department of the Board of Health in which examinations of the various ejecta including sputum will be made at short notice free of charge, there is not the slightest excuse for the very busiest man to neglect the precaution of early sputum-examinations.

That the privilege is not taken advantage of to any extent however, I think an examination of the records of that department of the city's government will show. Moreover, doctors who live far from such centers as Philadelphia and New York cannot have the advantage of such departments. To them, I am sure, such an examination of sputum of all suspicious cases is a practical procedure.

Necessarily a working knowledge of a microscope and the ability to recognize various organisms when seen under the microscope, are indispensable. All recent graduates have that knowledge, or should have it. The young men are always anxious and willing

to help the older with or without a compensation, and can be utilized much to the young physician's benefit as well as that of the patient. Anyone, however, with a little practice can learn to speedily and accurately examine a sputum-specimen.

The necessary apparatus is: a microscope, preferably with an oil immersion lens, though lower powers may be used, an alcohol lamp, a bottle of fuchsin, a bottle of Gabbet's counter-stain, some cover-slips and glass slides. Some sputum having been obtained, a small bit of the sputum is put upon a slide and covered with a slip, this is examined with a low power, $\frac{1}{4}$ or $\frac{1}{2}$ inch for foreign bodies such as elastic tissue or the various larger organisms. Another small bit, preferably a small caseous mass, is spread between two slides very thin. The slides are separated and allowed to dry in the air. One is then passed three or four times rather slowly through a Bunsen jet, or, if that be not at hand, through the flame of an alcohol lamp. Upon this is placed some carbol-fuchsin until the whole part of the slide covered with sputum is covered with the stain.

This is heated very slowly and gently until steam is seen rising from the slide. It is allowed to stand one or two minutes. The stain is allowed to flow off the slide, and the portion previously stained with fuchsin is covered with Gabbet's stain, which is allowed to stand for two or three minutes. This is then washed in water and dried by the use of a blotter. Some cedar oil is then placed directly upon the stained sputum and the oil-immersion lens run down until the particles are in focus. The specimen will be seen to have a uniform blue hue—cells, bacteria and a corpuscles all being stained blue. If tubercle-bacilli be present however, they will be seen as small red rods in the blue field. Accurate plates of this can be seen in Mallory and Wright or in von Jaksch.

This method of staining for tubercle-bacilli is preferable to the use of the cover-slip. There is no danger in the various manipulations in breaking a slide, whereas a cover slip cracks except in the expert hands. The whole procedure will take not more than 15 or 20 minutes. Surely time well spent.

It appears to me that Austin Flint's statement made in 1882: "I predict that the time will soon come when in order to corroborate the diagnosis microscopical examinations of the sputa will be considered as much a matter of course as examinations of urine for evidence of renal disease," should be ever present to all of us, if for no other reason than that early diagnosis of tuberculosis can thus be made and myriads of bacilli be destroyed that would otherwise be a source of infection.

RESECTION OF THE RECTUM PER VAGINAM.*

By JOHN B. MURPHY, A.M., M.D.,
of Chicago, Ill.

Professor of Surgery, Northwestern University; Professor of Surgery, Chicago Postgraduate School and Hospital; Professor of Surgery, Chicago Clinical School; Attending Surgeon, Cook County Hospital, Mercy Hospital, and Alexian Brothers' Hospital; Consulting Surgeon to St. Joseph's Hospital and Hospital for Crippled Children.

It is not the purpose of this paper to consider in detail the pathological conditions, such as fibrous stricture, tubercular disease, neoplasms, and so forth, which may

* Prepared for the Southern Surgical and Gynecological Association, Atlanta, Ga., 1900.

demand removal of the rectum. These have been admirably treated in the recent work by Quenu and Hartmann, and involve such an extensive study that we will but mention them here.

The profession has not yet agreed upon a definite and satisfactory technic in the performance of proctectomy, as it has in hysterectomy and many other pelvic operations. The posterior operations, such as the transsacral and ischiorectal, have, in the last decade, attracted most attention and found many advocates, but

FIG. 1.

that they are difficult, dangerous, and in many respects ultimately unsatisfactory, is beyond question. The mortality in 14 of the largest European clinics is 21.2%. (Pruz.)

The perineal proctectomy of Volkmann is applicable only to carcinoma involving the third and lower half of the second portion of the rectum. The vaginal route has been overlooked, or at least greatly slighted, and notwithstanding the fact that a number of operators have been forced by the pathological conditions present to make use of it, in only a few instances has it been the method of election.

The procedures resorted to for rectal extirpation may be classified as follows, partially after the plan of Renzaldt and Stintzing:

1. Bloodless dilation of the sphincter. (Simon.)
2. Circular incision around the anus. (Lisfranc.)
3. Perineal methods:
 - a. Posterior division of sphincter. (Dieffenbach.)

- b. Posterior longitudinal incision with retention of the anus and sphincter. (Kocher.)
- c. Resection of coccyx. (Kocher.)
4. Transsacral method with resection of portions of sacrum:
 - a. One-sitting. (Kraske: In America, Fenger.)
 - b. Transverse section. (Bardenheuer, Rose.)
 - c. Oblique section. (Hochenegg.)
 - d. Transverse resection of sacrum and coccyx. (Heineke; Schlange; Kocher; Hegar; Rydygier; Mancy.)
5. Parasacral methods, division of soft parts on side of sacrum without section or excision of sacrum or coccyx. (Zuckerkindl; Wölfler; Schelkly.)
6. Vaginal extirpation. (Des Quins; Norton; L. L. MacArthur; Campenon; Rehn; Vautrin; Price; Byford; Bristow; Julius Sternberg.)
7. Primary vaginal celiotomy, examination of extent of disease and then complete division and later excision with end-to-end union of intestine—retention of sphincter. (Rehn; Murphy after method to be described herein)

FIG. 2.

DEVELOPMENT OF THE VAGINAL OPERATION

1. In July, 1890, DesQuins¹ in a case of carcinoma of the rectum involving the rectovaginal septum, removed the septum with the tumor, drew down the sigmoid and sutured it to the anal portion of the rectum, which he had retained. The peritoneum was not closed by suture. The defects in the perineum and vaginal wall were closed by suture, silver wire being used for the former. The patient died shortly after operation, but it was noted that there was immediate continence of feces. Cause of death was not given.

2. December 17, 1890, A. T. Norton² removed a carcinoma

of the anterior rectal wall, not involving the vaginal mucosa, by complete division of the perineum without opening the peritoneal cavity. He excised the entire lower segment of the rectum, including the sphincter, and sutured the proximal end of the bowel to the skin. The patient had fecal continence one month after operation.

3. In 1891, L. L. MacArthur³ in a secondary operation for recurrent carcinoma of the rectum, removed the diseased portion of the bowel and sutured the proximal end into the upper portion of the vagina. The operation was followed by good results.

4. Campenom, in 1894,⁴ performed a resection of the

FIG. 3.

rectum for nonmalignant stricture, not involving the vaginal wall. His incision was in the rectovaginal septum, extending out onto the perineum, which, however, was not completely divided. End to-end approximation of the proximal bowel with the anal portion, which had been left intact, was accomplished by means of sutures. Patient recovered, stricture did not return, and she had sphincteric control.

5. In 1895, L. Rehn⁵ removed a carcinoma of the rectum by division of the perineum and later opened the peritoneal cavity. Death from peritonitis.

6. Vautrin,⁶ in May, 1895, removed a carcinoma of the rectum per vaginam. The details of the operation are not given in the report.

7. In 1896, Joseph Price⁷ reports an operation performed by himself, for carcinoma of the uterus and rectum. He did an anteroposterior hysterectomy, removing the rectum with the uterus, and subsequently suturing the proximal end of the bowel into the vaginal wall. The patient recovered from the immediate effects of the operation, but died on the seventh day. Subsequently he performed an operation in which he utilized the button as a means of approximation.

The case recovered, and is probably the first case of approximation of this kind on record.

8. In November, 1896, Dr. H. T. Byford⁸ reported a case of excision of a rectal carcinoma by incision through the upper portion of the vaginal wall. In his efforts to draw down the remaining portion of the rectum, the peritoneal cavity was torn open. The proximal end of the bowel was sutured into the upper part of the posterior vaginal wall, with the intention of similarly suturing the anal segment into the lower part, and closing the vaginal orifice, thereby converting the vagina into a portion of the fecal tract. He does not state the result, but mentions that in a later case he successfully performed the operation, the patient surviving for 1 year.

9. Bristow,⁹ in 1896, removed a carcinoma of the rectum through the posterior vaginal wall, without opening the peritoneum. His case recovered, and in comment he says: "Farther than 6 inches it is not possible to go, judging from my experience in this case."

10. Julius Sternberg¹⁰ reports from Gersuny's Clinic in

FIG. 4.

Vienna, 14 cases of resection of the second and third portions of the rectum through the posterior wall of the vagina. All were cases of malignant disease. His results were 12 recoveries and 2 deaths. In some of the cases where the peritoneum was accidentally opened, it was closed with sutures. The sphincter was retained when not involved in the disease.

11. From Rehn's clinic, Liermann¹¹ reports 2 cases, 1 operated on July, 1897, in which the rectum and uterus were both removed, 17 cm. of the former, and in the other case, operated on January, 1898, the rectum alone was excised. Both patients recovered and both had sphincteric control.

Thus we find the operation of vaginal proctectomy advancing in the direction of the peritoneum and sigmoid, without any definite plan as to a vaginal celiotomy for the removal of carcinoma of the first portion of the rectum or lower portion of the sigmoid.

Anatomy.—A few details of the anatomy of the sigmoid and rectum may be considered here as they are important in the performance of this operation. The normal position of the sigmoid is in the pelvis and not in the left iliac fossa as is generally supposed. It be-

FIG. 5.

gins at the outer border of the left psoas muscle, just above the brim of the pelvis, crosses the muscle at a right angle, descends vertically along the left pelvic wall sometimes as low as the floor of the pelvis, then passes horizontally to the right pelvic wall and occasionally upward into the right iliac fossa, where I have encountered it in operating for appendicitis. From here, after sharply flexing upon itself, it passes to the left as far as the median line, where it becomes the rectum and descends to the anus. It is supported by a mesosigmoid, whose line of attachment crosses the left psoas muscle, curves upward, passes over the bifurcation of the common iliac vessel and then passes downward on the left side of the pelvis to the median line.

It will be seen from the attachments of the mesosigmoid that this portion of the bowel can be reached and resected from below. The mesentery measures from $1\frac{1}{2}$ to $3\frac{1}{2}$ inches in length, thus permitting great freedom

of motion in the pelvis, which is necessary in the performance of one of its great functions; that of guarding against the extension of pelvic infections.

The sigmoid may rotate on its axis in a scroll-like manner and be completely surrounded by its mesentery, this being possible because of the length of the latter. It occasionally becomes adherent in this position and produces the train of symptoms known as ileus. These symptoms are produced in the presence of the above condition, when the bowel becomes over-distended and forms a sharp kink. I have operated upon two cases where the obstruction was caused by this type of adhesion.

The rectum is usually described as having three distinct portions, but more correctly there are but two. The first portion begins at the third piece of the sacrum and extends to the tip of the coccyx. There is no mesorectum and it is covered by peritoneum only at its upper part on the anterior surface. It is $3\frac{1}{2}$ inches long,

FIG. 6.

and behind is in relation with the sacrum and coccyx, whose curves it follows. In front it is in relation with the trigon of the bladder and seminal vesicles in the male, and in the female with the vagina and cervix uteri. The peritoneum in the male comes to within 3 inches of the anus. I found on the male cadaver that 11 inches of rectum and sigmoid could be resected through a median and lateral perineal incision. The second portion, formerly described as the third, is $1\frac{1}{2}$ inches long, and extends from the tip of the coccyx to

the anus. Below it is surrounded by the external sphincter, and above, about 1 inch from the anus, by the internal sphincter, which is half an inch broad.

CASE 1.—Referred to me by Col. Nicholas Senn (then in the service at Chattanooga), Mrs. M. W. S., aged 36, occupation, housewife. Admitted to Mercy Hospital July 12, 1898.

Present illness: Ten or 12 months ago, patient began complaining of indefinite pain in the lower abdomen and upper portion of the vagina. About 6 months ago she first noticed bloody and mucous discharges from the rectum, and the feces assumed a ribbon shape. The diagnosis of "bleeding piles" was made. Examination revealed a malignant tumor of the first and second portions of the rectum, for the removal of which operation was advised. The patient was very fleshy, and the perineal, hemorrhoidal, and vaginal veins were enormously distended. Extent of disease shown in Fig. 1.

Fig. 7.

Operation, July 16, 1898. Lithotomy position. The vagina was dilated with broad speculæ, the cervix draw down, and the culdesac opened by a transverse incision similar to that used in vaginal hysterectomy. Large laparotomy sponges were now passed into the peritoneal cavity to displace the intestines out of the field of operation. The tumor was carefully examined, as well as the rectoperitoneal lymph-glands, which latter did not appear to be involved in the disease. The tumor extended upward almost to the brim of the pelvis. The rectovaginal septum was now divided down to the rectum by a vertical incision in the middle line, extending from the postcervical opening, and including the sphincter ani. (Fig. 2.) The hemorrhage, which was quite profuse from the dilated veins, was controlled by compresses and forceps. The posterior vaginal wall was now dissected laterally from its attachments to the rectum; lateral and anterior retractors were placed in position, and a large field

for operation exposed. (Fig. 3.) The sigmoid could be handled throughout its entire extent, and brought well down without the slightest difficulty. With scissors the anterior rectal wall, including the sphincter, was divided up to the lower border of the tumor, and the anal segment of the rectum separated from that just above it by a complete transverse incision one inch below the lower limit of the tumor, the incision extending into the postrectal connective tissue. (Fig. 4.) The proximal end of the rectum was grasped with vulsellum forceps, closing it completely and, by the use of curved scissors separated from its coccygeal and postrectal attachments, upward to the promontory of the sacrum, thus freeing and mobilizing it. (Fig. 5.) The hemorrhage during this part of the operation was easily controlled. The mesosigmoid was now loosened sufficiently to allow the healthy portion of the bowel to come well down. The rectum was amputated above the upper border of the tumor growth, and the sigmoid and sphincteric segment of the rectum united end-to-end by silk sutures. These sutures were passed from within outward, thereby causing all the knots to be on the inside of the bowel; the ends were left long to facilitate removal. The incision in the anterior rectal wall was closed with silk sutures, introduced in the same manner as those last described, and the ends of the divided sphincter were united by buried sutures of catgut. (Fig. 6.) The laparotomy sponges were removed from the peritoneal cavity and the peritoneum on the floor of the pelvis closed with a continuous catgut suture. The vaginal wall was sutured to the cervix, closing the transverse incision, and the edges of the vertical cut united in the central raphe with silk-worm-gut sutures. (Fig. 7.) A large rubber drainage tube, one inch in diameter, was inserted into the rectum and sutured in place.

When the patient was returned to her room the pulse-rate was 86 and temperature 97.6°. The highest temperature and pulse-rate occurred 28 hours after operation, when the former registered 100° and the latter 101 per minute. Convalescence was uneventful. After removal of the rectal tube it was noticed that there was a slight fecal discharge through the vagina when the bowels were loose. This sinus was operated upon a short time later, and the patient discharged, cured, September 1.

Pathological report on specimen of rectal tumor, July 20, 1898, by Dr. W. A. Evans, was as follows: "The tumor is malignant, a cylindrical-celled carcinoma. There is a piling up of the epithelia in the mucosa, and the submucosa is occupied by epithelial cells. The muscularis mucosae cannot be recognized. The epithelium shows abundant traces of its glandular antecedents. In places the invasion of the muscular coats by the epithelial cells is evident, and there are also to be seen in this layer areas of round-celled infiltration, showing an inflammatory process."

August 17, 1899, I received a letter from the husband of this patient, stating that she had suffered considerably since March from a strictured condition of the rectum and prolapse of the uterus, the latter organ seeming to press upon the former. After a few dilations with the bougie and tampon the obstruction disappeared and the uterus remained in position. In a still later letter the patient states that the stricture has again recurred. At the present time I have not had an opportunity to examine her, but expect to do so in the near future.

CASE 2.—Mrs. D. B., aged 67 years; housewife. Admitted to West Side Hospital May 22, 1899.

Present illness: Three years ago the patient began to have severe "diarrhea," which persisted for 6 months. The passages were frequent, often 20 a day, liquid in character, and accompanied by tenesmus. After 6 months some improvement took place, but during the next year she had frequent similar attacks. For the past 18 months she has passed considerable blood and mucus from the bowels and the stools have been very frequent. Gripping pains in the abdomen and tenesmus have been very severe during the same length of time. Has lost 40 pounds in weight during the past 1½ years.

Previous history: Patient had usual diseases of childhood. The menopause occurred 15 years ago; has had 10 children, all living and well. Family history: Mother died of "cancer of the stomach." Otherwise negative. Examination of patient: Somewhat emaciated. Heart, lungs, and abdomen negative. Rectum: Hard, ulcerated tumor is found on

digital examination, involving the first and second portions.

Operation, May 30, 1899: An operation exactly similar to that described in Case 1 was performed. Time of operation, 1 hour and 15 minutes. Bowel-movement through the rectal tube, which was inserted at the completion of the operation, occurred in 12 hours. The vaginal packing was removed in 72 hours. On the fifth day a slight fecal discharge through the vaginal wound was noted. On the twelfth day the rectal tube was removed. Stitches were removed on the fourteenth day after operation, and on the fifteenth day the patient sat up and had a natural, voluntary bowel-movement. There

FIG. 8.—1. Glandular tissue in mucosa. 2. S. mucosa.

was still some fecal discharge into the vagina at this time. On the twenty-ninth day following operation, as the fecal discharge continued, it was decided to close the rectovaginal fistula by operation. The edges of the fistula were freshened and approximated by means of interrupted sutures of silk-worm-gut. Tube inserted into rectum and retained in place by a suture. After second operation, convalescence was uneventful and patient was discharged from the hospital, with all wounds entirely healed, July 17, 1899.

Dr. A. W. Chandler, of Compton, Ill., who referred the case to me, states that at the present time there is no evidence of recurrence of the disease, the patient is in excellent general health and has full control of the bowels. The rectovaginal fistula has remained closed.

CASE 3.—Mrs. E., age 40 years, housewife, admitted to the Mercy Hospital January 24, 1899. Present illness: For some time patient has complained of slight irritation and pain in rectum during defecation. The general health is good. Examination of the patient reveals an ulcerated area with raised slightly indurated borders, situated on the posterior rectal wall, about 2 inches above the sphincter ani.

Operation, January 26, 1899. The sphincter was dilated, ulcer brought down with vulsellum forceps and excised. The edges of defect united by means of silkworm-gut sutures, perforated shot being used for retention. Patient was discharged from the hospital, February 18, 1899, improved. Examination of tumor showed it to be a simple adenoma.

Readmitted to Mercy Hospital May 4, 1900, suffering from recurrence of the symptoms mentioned above. Examination of the rectum showed an ulcer, situated on the posterior wall about 1½ inches above the internal sphincter, apparently involving the mucous coat only.

Operation, May 5, 1900. Sphincter dilated, ulcer drawn down and excised by cutting well outside its borders. Edges of rectal wall drawn together with catgut sutures. A gauze drain was left in rectum. Patient discharged May 20, 1900.

Admitted to Mercy Hospital for the third time September 11, 1900, complaining of the same symptoms as before, with some bloody discharge from the rectum. Examination showed an indurated mass involving the posterior wall of the rectum at site of former operation and extending upward.

Operation September 12, 1900. The diseased portion was resected after the method described in Case 1. No unpleasant symptoms followed the operation, except a rise in temperature which took place 36 hours later and persisted from 100° to 101.5° until September 22. A slight fecal discharge into the vagina was noted several days after operation, but at no time became profuse. Almost immediately there was sphincteric control, weak at first, but gradually growing stronger during convalescence, until date of discharge, November 5, when it was almost complete. Recto-vaginal fistula had closed when patient left hospital.

Microscopic examination of specimen shows it to be composed principally of adenomatous tissue (Fig. 8), with beginning proliferation of epithelial cells in the deeper layers of the rectal wall. (Fig. 9.) Carcinoma.

CASE 4.—Mrs. K. P., age 31 years, housewife. Admitted to Cook County Hospital October 16, 1900. Present illness: About 7 years ago patient was first troubled with constipation, which has gradually grown worse until the present time, compelling her to use cathartics and enemata daily. Has considerable pain on defecation. Has never passed blood from bowels. Two years ago, after confinement, patient had "childbed fever" which kept her in bed for nearly 4 months. After this she experienced bearing-down pains in the pelvis and back, aggravated whenever she assumed the erect position. States that her "womb seems to fall" and has noticed a portion of the cervix protruding from the vulva.

Previous history: Measles in childhood. Rheumatism about 8 years ago, sick for 1 year. Never had severe diarrhea nor dysentery. Knows of nothing that might have caused her constipation. Denies all venereal infection. Began to menstruate at sixteenth year, always regular, flows about 4 days at each period. Two children, first about 16 years ago, second about 2 years ago, after which patient had the fever. One miscarriage about 5 years ago, no trouble following.

Habits: Uses liquors and morphin. Family history: Negative. Examination: Heart, lungs, and abdomen negative. Vaginal: Uterus prolapsed, anterior, posterior and lateral vaginal walls bulging into vagina, and entire uterus low and poorly supported. An old laceration of the perineum causes the lax vaginal outlet and is evidently responsible for the displacement. Rectum: About 2½ inches above anus is an

FIG. 9.—1. Small arteries in rectal intima. 2. Dense fibrous tissue. 3. Area of round cell proliferation.

annular stricture hard and movable; cicatricial tissue completely surrounds the rectum and the opening admits only the finger tip; the surface is not ulcerated.

Operation, November 10, 1900. Stricture removed by resecting rectum through vagina and opening the peritoneal cavity. Sphincter was retained and showed firm contraction at completion of the operation.

At the present date, January 11, 1901, there is partial failure of the perineal union, but an excellent end-to-end approximation of the bowel. The perineum will be repaired by the ordinary method.

CASE 5.—Miss N. E., age 26 years. Occupation, Clerk.

Single. Admitted to Cook County Hospital, December 3, 1900.

Present Illness. Three and one-half years ago patient fell from a bicycle, severely bruising the muscles over the left ischial tuberosity and causing an abscess near the rectum, which ruptured spontaneously. It remained an open sore for two weeks, then the wound healed, but subsequently a second abscess in the same situation had to be opened by a physician. After this a small opening, the size of a pin-head, remained for seven months, at the end of which time an operation was performed and the sinus was incised and drained. Wound healed in five weeks. One year later a yellowish discharge began to flow from the old wound; other openings at some distance from the anus were formed. Previous illnesses: As a child had infectious diseases. Six years ago erysipelas. Back was injured by being shut up in folding bed five years ago. Menstruation began at 13 years, always normal, until one year ago when it became scanty. Denies all venereal infection and gives no history of syphilis.

Examination: Skin over left ischial tuberosity is perforated with a dozen or more fine openings leading into sinuses which communicate freely. Skin is indurated and thickened but almost painless on pressure. Sinuses do not extend deeply into muscular tissue. The clinical appearance is that of lupus. Rectal examination: Reveals a narrow circular stricture of the rectum about $2\frac{1}{2}$ or 3 inches from the anal opening. Above the stricture there is an ulceration extending

FIG. 10.—a. Small artery-proliferating intima. b. Dense fibrous tissue. c. Areas of round-cell proliferation.

upward $2\frac{1}{2}$ inches. The stricture is movable. Vaginal examination negative. Back: Several vertebrae in the lower dorsal region project, though there is no tenderness or evidence of inflammatory processes. Lungs and heart negative. No tubercle bacilli found in the sputum.

Operation: December 14, 1900. Rectum resected through the vagina by the method described under Case 1, $2\frac{1}{2}$ inches removed. Peritoneum closed. Postrectal drainage.

Examination of patient, January 17, 1901. For past four days patient has had complete control of the sphincter. Previous to that it was partial. Rectovaginal septum and perineal body have united, leaving no fistulous communications. Rectal tube, which was inserted at the time of operation, was removed after eighteen days and the sutures have been taken out since. Sphincter contracts on the finger when inserted into the rectum, but not with normal vigor. Skin lesion which was present over the buttocks before operation, has materially improved. Microscopic examination of the tissue removed it as follows: The mucous membrane, where present above stricture, is of about normal thickness. The tissue producing the stricture is composed principally of dense fibrous bands, with scattered areas of small round-celled infiltration. No epithelioid or giant cells found and there is an entire absence of caseous degeneration. Endarteritis obliterans is a prominent feature throughout the sections, which would lead us to suspect that the process was syphilitic rather than tubercular. (See Fig. 10.)

Conclusions.—The advantages offered by the vaginal route are:

1. The sacrum and posterior bony wall of the pelvis are not disturbed.

2. The field of operation is as extensive and the anatomical parts as accessible as in the transsacral operations.

3. The peritoneal cavity is opened in both the vaginal and sacral operations, and in neither is it a source of great danger.

4. The diseased tissue is more accessible for inspection and the extent to which the operation may be carried in an upward direction is as great, if not greater, than by the sacral route.

5. The peritoneum may be drained freely through the vagina.

6. A perfect end-to-end approximation, either by suture or by the use of the button, may be secured. The preferable method of uniting the two ends is by interrupted sutures of silk, because as there is no peritoneum on the sphincteric segment, failure of union with the button is to be feared.

7. The sphincter is retained and the perineal body is restored. There is diminished action of the levator ani muscle.

8. When the operation is complete, the parts are practically in their normal positions.

I have performed the same operation on the male cadaver and find that by splitting the sphincter directly through the median line, anteriorly and posteriorly, cutting back to the coccyx and opening the rectovesical fold of the peritoneum, practically the same field for operation can be obtained as in the female. Several inches of the bowel can be excised and end-to-end union secured. Either anteproctaeal or postproctaeal drainage may be used. The cut ends of the sphincter are united anteriorly and posteriorly. The lateral nerve-supply on either side is not disturbed.

AMPUTATION OF BOTH FEET UNDER SPINAL ANESTHESIA WITH COCAIN.*

By AUGUSTUS C. BEHLE, M.D.,

of Salt Lake City, Utah.

MR. PRESIDENT AND GENTLEMEN:—I wish to report to you this evening a case of amputation of both feet in which I used a subarachnoid injection of cocain for anesthesia. My patient, Mr. H. A. Woodmansee, on New Year's Day of this year, was thrown from his horse while returning from the mountains where he had been locating some mining claims. It was about 2 A.M. and the night intensely cold, there being 4 or 5 feet of snow on the ground. Mr. Woodmansee was rendered unconscious by his fall and does not remember how long he remained in the snow. When he regained consciousness he did not know where he was and wandered

* Read before the Salt Lake County Medical Society, February 11, 1901.

around until daylight, finally reaching Ophir. His shoes were then removed by cutting them to pieces. The feet were immersed for 4 hours in snow water, followed by rubbing with olive oil, from 11 P.M. until 5 A.M. He was then taken to Tooele, where he remained under the care of a physician until the following day. Being removed to this city he was placed under my care; I advised him to go to St. Mark's Hospital. Both feet were badly discolored and cold. One foot was covered with blebs which were filled with a bloody serum; the legs half way up to the knees were intensely red, hot, swollen, and tender. The patient was poorly nourished and intensely nervous from the exhaustion and exposure. Sustaining the strength of the patient, attention to the partly frozen tissue, and avoiding general sepsis by preventing a moist decomposing gangrene, was the treatment instituted for the next three weeks. The line of demarcation being well shown at the end of this period and the patient realizing that he could not save his feet, we decided upon amputation.

In selected cases I have been using local and regional anesthesia in minor and major surgery in place of general anesthesia. The immediate deleterious results of a general anesthetic are only too common in our routine use of these agents. Of the remote results we know too little. I believe that many chronic inflammatory lesions of both lungs and kidneys could be avoided by the judicious choice of anesthetic agents. The latest form of regional anesthesia is the subarachnoid injection of cocain solution.

This method has had the careful attention of our scientists for the past few months in a practical way. "It has been weighed in the balance," and, in my opinion, has not been found wanting. While I am not here to advocate its use in every case where it can be used, I firmly believe that now we have a new procedure that will prove a boon to suffering humanity. A skilled anesthetist is a necessary factor in every major surgical operation, if you wish to give your patient the care that is necessary to avoid his succumbing from the anesthetic itself. Gentlemen, picture to yourselves a country practitioner amputating a leg with one eye on the knife and the other on the relative or friend giving the anesthetic under his direction. Probably he will have to leave his knife and pull out the retracted tongue of the patient, then wash his hands again—of course he will not forget this in his haste to resume his work. On the other hand, think of the same practitioner with his hands sterilized, inserting a needle into the lumbar subarachnoid space, injecting a little solution, withdrawing his needle and then proceeding with his amputation with his hands remaining unsoiled. No fear or worry that the patient will not regain his consciousness. When Dr. Leonard Corning announced his discovery of this mode of anesthesia in 1885, little attention was paid to it, as he did not make a practical use of this method in surgical work. In 1899, A. Bier, of Kiel, used the subarachnoid injection of cocain by means of Quincke's lumbar puncture upon his assistant, Hildebrand, and in turn was himself anesthetized by this method. Following this, Tuffier took up this work and made the method popular. Experimenting for some time with minor surgical cases, he began to do major surgical operations under this anesthesia. Before the section on surgery at the International Medical Congress at Paris, in August, 1900, many major operations were reported, and this mode of anesthesia and operations following were demonstrated. Reports

have followed each other rapidly, some writers advising the use of this form of anesthesia in every case where it can be used, others advising its use in selected cases. One of the most interesting reports that I have seen is from the pen of S. Marx, who studied its action in relieving the pain of labor. As he expresses it, "to see the parturient woman under the influence of cocain, lie quietly in bed, feeling only some indescribable sensation, but without pain; bearing down when told to, and giving birth to her child without her knowledge, and only cognizant of the fact when the cry of the newborn was heard," would astonish any one of us as it did him.

To avoid the shock and depressing effects of general anesthesia and having had experience in performing the lumbar puncture for diagnostic purposes, I determined to use this method of anesthesia on my patient. Stating the case to him he readily consented, as he feared the general anesthesia more than the operation itself. I injected 15 minims of a sterile 2% solution of cocain into the lumbar subarachnoid space and in two minutes had a profound anesthesia of all tissues below the tenth rib; the anesthesia lasting almost 2 hours. Assisted by Dr. Landenberger, I rapidly amputated the limbs, the patient being back in bed some time before the anesthesia subsided. I am pleased to state very little shock followed the operation. None of the sequelae, such as nausea, vomiting and headache, which some surgeons have reported after the use of this method, were observed. My patient took a little whisky and strychnia by mouth about half an hour after the operation and began to take nourishment immediately. He was prepared the same as for general anesthesia by having empty bowels and stomach, which may account for the lack of headache and nausea in my case. I wished to be prepared for ether or chloroform anesthesia in case the regional anesthesia was not satisfactory. The rise of temperature after the operation was very slight, being only a fraction above 99° F. My patient made a rapid recovery, the stumps healing by primary intention. He was discharged from the hospital on the fifteenth day after the operation and the stumps could be handled with very little pain to the patient. I cannot see how anything more could be desired.

SARCOMA OF THE RIBS.

By C. C. WARDEN, Ph.B., M.D.,

of Nashville, Tenn.

Professor of Anatomy and Operative Surgery in the Medical Department of the University of Nashville.

T. B., aged 28, civil engineer. Previous health good until a year and a half before the present illness when he was sick for two weeks with malaria. In June, 1899, he had an attack of intercostal neuralgia on the left side. From this attack he recovered fairly well, but within a month another and more severe attack came on. During August there were repeated paroxysms of neuralgia in the same region, and in September he had three attacks of "renal colic," all on the same side.

Early in October sciatica developed on the right side. The seizure was very severe and the patient was taken to Hot Springs in search of relief. He returned after a fortnight, unimproved. There was extreme pain and tenderness along the right sciatic and popliteal nerves with numbness in the heel and some anesthesia in the leg. The temperature and pulse were normal.

Pain now made itself felt in the scalp and neck. In the middle of November sciatica set in on the left side and for a

week the man suffered with paroxysms of agonizing pain, when suddenly the sciatica in the right side disappeared, never to return. Late in the month a firm, immovable tumor-like mass was made out over the eighth, ninth, and tenth ribs on the left. There was no pain, tenderness or redness and the overlying skin was freely movable. Careful questioning now elicited the statement that an injury in this region was received from a fall during a game of tennis nearly two years ago.

In December the patient complained of failing sight in his right eye. Emaciation and loss of strength now became progressive. The abdomen became distended and tympan-

FIG. 1.—The primary sarcomatous growth on the ribs.

itic. There was no pain, but some tenderness and rigidity were observed in the right iliac fossa.

The patient's condition prompted the suggestion of an exploratory operation, which was accepted.

The abdomen was opened on December 14. The viscera everywhere within sight and touch were enormously thickened, grumous and friable. No attempt at further procedure was made. The patient died the following day.

The autopsy showed the following conditions: Numerous hemorrhagic spots of small size covered the abdomen in irregular distribution. On the left side of the thorax was a moderately firm mass elliptical in outline, covering portions of the eighth, ninth and tenth ribs at their middle third. The right eye protruded prominently and was divergent. The tissues of the scalp over the occiput were thickened. On raising the scalp the tissues covering an area an inch or more in diameter resembled a superficial abscess, exuding on pressure a thick white substance. The thickened margins of the supposed abscess were closely adherent to the bone, while the center was soft and communicated with carious, spongy bone. On the surface of the dura directly beneath the carious bone was a mass two inches in diameter and a half an inch thick, semisolid and grayish white in color. The dura was smooth and free on its internal surface. The brain was normal. Beneath the periosteal covering of the right orbital roof was a softened mass similar in color and consistence to that in the dura. A chain of enlarged mediastinal glands covered the anterior aspect of the pericardium, identical in appearance, when incised, with the growth in the dura mater. The heart showed on the anterior surface a grayish-white, slightly elevated spot, three quarters of an inch in diameter, dipping a third of an inch into the muscle. A few small atheromatous patches occupied the first two inches of the aortic lining.

In the left side of the thorax, covering the middle portions of the eighth, ninth, and tenth ribs, was an ovoid mass the size of a child's head, adherent throughout to the visceral layer of pleura. The tumor, together with portions of the ribs to which it was attached, was removed for further examination. The bronchial glands were enlarged.

The peritoneum was thickened and fibrous. The omentum, free from adhesions, was an enormously thickened, mottled, grumous-looking mass, presenting here and there whitish areas resembling small abscesses. Many of the omental veins were thrombosed. The mesentery was greatly thickened and some of its glands were as large as walnuts. The proximal portion of the ileum presented a firm mass, about an inch in length, involving one half of the circumference of the gut and located on the side of its mesenteric attachment. This growth involved all the coats of the bowel and projected a half-inch into the lumen, showing on sec-

tion a pinkish-white color. Further toward the paroximal extremity of the small intestine was a portion sharply curved on itself, uniformly thickened and infiltrated. On one side, near the mesenteric border, the tissues were completely disorganized down to the mucosa where the necrosis terminated in a yellow patch about the size of a lentil.

The cecum was uniformly $\frac{3}{4}$ of an inch thick, grayish white on section and deeply injected on its mucous surface. There were no evidences of recent or old ulceration. The appendix was 5 inches long and sharply kinked from thickening. Two obliterating strictures were found in it, the dilated lumen between the constrictions being filled with a translucent jelly.

The liver, gallbladder and ducts and the stomach were normal. The pancreas was enlarged and softened almost to disintegration. The external appearance of the spleen suggested the presence in its center of a spherical body like a tennis ball. (Fig. 2.) On section the pulp at the periphery was normal in appearance. The center of the organ was filled by a spherical mass two inches and more in diameter, soft, grayish white with pinkish and hemorrhagic areas here and there. (Fig. 3.) The kidneys were enlarged and firm, with capsules slightly thickened and adherent. On section the cortices presented a congested appearance and the contrast between cortices and pyramids was less marked than normal. Numerous grayish-white masses of sizes varying from bird shot to buck shot were irregularly scattered through both organs.

The spinal canal and pelvic contents were not examined. Cultures taken from the softened portions of the growths in the dura, orbit and elsewhere produced but one variety of organism, the *Bacillus coli communis*.

Microscopical examination of the tumor on the ribs and the various disseminations in the viscera showed small round-celled sarcoma. (Fig. 4.)

The gross specimen of the tumor on the ribs was of considerable interest. (Fig. 1.) The length was $4\frac{1}{2}$ inches, breadth $3\frac{1}{2}$ inches, the third diameter measuring $2\frac{3}{4}$ inches. Fully two thirds of the mass occupied the internal surface, the plane of the ribs passing through the outer third of the growth. The mass was semisolid and on section presented a grayish-white appearance marbled with areas of a delicate pink. The center was red and hemorrhagic. The growth was of the periosteal variety.

A review of the literature pertaining to this interesting pathological condition gives for analysis a total of

FIG. 2.—Spleen, showing central location of the spherical mass.

73 cases, including the one herewith reported. The cases are so few in number that the task of sifting out cross-references and identifying those twice and thrice reported is no idle one. This review is intended to embrace only cases of the type implied in the title. Consequently all tumors of the sternum, spine and soft parts have been excluded, together with all types of tumor other than sarcoma. All doubtful cases have been omitted. Gay's case⁴ proves to be a chondroma and is not included. Out of the total number of cases

65 came to operation. By far the ablest reviews of the operative treatment of tumors in the chest-wall are those of Campe,¹ Gerulanos,² and Parham³ of New Orleans. Parham's valuable monograph discusses fully all cases of resection for tumors of all types growing from the bony wall of the chest. Some of König's cases, reported by Campe, should be added to his series. Of the 8 inoperable cases one recovered. The total mortality is 48%. In operable cases a slight improvement is observed, there being 28 instances of recovery,

FIG. 3.—Spleen laid open.

or a mortality of 38.3%. If we add to the list of deaths following operation the doubtful cases and those the result of which is not given the death-rate rises again to 46.7%. It will be safe to say that this figure is not excessive, since many of the patients reported cured by operation were not kept under observation for a length of time sufficient to exclude the possibility of recurrence. Five cases in the series give clear histories of recurrence, 3 of which were subjected to secondary operation, 2 died and 1 recovered. Fully $\frac{2}{3}$ of the patients were males. In two instances the sex is not given. The youngest male was 10 years old and the oldest 66. The extremes of age in females are 10 and 45. No cases appear during the first decade of life or after the sixth. Fully $\frac{1}{2}$ of the cases occur between the ages of 20 and 30 and over $\frac{2}{3}$ between 10 and 30. The relation of injury to the morbid process is difficult to trace, and the results of its investigation are somewhat disappointing. Gross says that trauma is an assignable cause of malignant disease in $\frac{1}{2}$ the cases. Dennis lays stress upon traumatism as being a distinct causative factor in sarcoma. There is a clear record of injury in 16 cases only, or 22%. A majority of the writers do not mention the subject. It is probable that this percentage index is far too low. The trivial nature of many a forgotten injury is responsible. Blows and falls upon the chest are causes most frequently noted, and fracture of the ribs comes last of all.

For the sake of convenience the conclusions noted above are arranged in the following table:

Whole number of cases, 73.
Operable cases, 65.
Inoperable cases, 8.
Total deaths, 35. Mortality, 48%.
Deaths in operable cases, 28. Mortality, 38.3%, including doubtful cases, 4, and result not given, 2. Mortality, 46.7%.
Traumatism, 16—22%.
Males, 47—64.3%. Youngest, 10; oldest, 66.

Females, 24, 32.8%. Youngest, 10; oldest, 45.

Sex not given, 2.

Ages, first decade, none.

" second decade, 2—21%.

" third decade, 25—48%.

" fourth decade, 7—13.5%.

" fifth decade, 6—11.5%.

" sixth decade, 2—3.8%.

" seventh decade, none.

Gurlt⁴ gives statistics obtained from the General Hospital and Rudolph Institution of Vienna covering 49 cases of sarcoma of thorax, ribs, and sternum, of which 19 were males, 21 were females, and 9 unknown. A note says that the data for this class are very unsatisfactory, as in many cases it is not known whether the soft parts or the bones or both were involved. No attempt was made to separate the cases into classes, and it is also stated that 5 of the General Hospital cases were in all probability carcinoma. The whole series is accordingly eliminated.

My thanks are due to Dr. W. G. Ewing for many privileges in connection with the case above reported, and to Dr. Larkin Smith for the accompanying illustrations.

Since the foregoing review was written the history of another case has reached me. The patient was under the care of Drs. C. S. and S. S. Briggs, of Nashville, and it is through the unfailing courtesy of these gentlemen that I am permitted to report it.

Mrs. R., Huntsville, Ala., aged 35, multipara, youngest child 6 years old. No abortions or miscarriages. General health good. Presented a hard, fairly smooth tumor, sessile and firmly attached to the ribs, situated in the upper left pectoral or subclavicular space, extending half way to the

FIG. 4.—Photomicrograph of metastasis in the kidney. Indistinct remnants of tubules may be seen here and there.

nipple below and overlapping the clavicle above. The inner margin reached the sternum and the outer border was lost in the axillary space. There was no perceptible glandular involvement. The left arm and hand were edematous and the seat of dull pain. The tumor was first noticed in February, 1900. It was painless and gave no trouble until the swelling in the arm appeared. She gave no history of injury. X-ray examination resulted negatively as no light penetrated that side. There were no chest symptoms. Heart-sounds were normal, but there was some pulsation in the jugulars. Operation early in November, 1900. Three ounces of A. C. E. mixture were used.

A curved incision was made over the tumor and carried through the pectoral muscles, exposing the neoplasm. After much effort the lower and inner sides were freed, then the upper side. The growth was found to spring from the periosteum of the first, second and third ribs. In freeing the outer portion the brachial plexus, axillary artery and vein were exposed. The vein was involved and would have required resection. The tumor tissue was cut through to relieve the vein and the growth removed. The intercostal muscles were infiltrated and there was evidently more growth inside the thorax. The wound was closed with wormgut sutures, and a large rubber tube was used for drainage. The sutures were removed on the seventh day, the wound having healed well. The patient was dismissed on the eleventh day. There can be but one outcome eventually in the case.

Microscopical examination showed the growth to be a sarcoma undergoing myxomatous change.

Another case has been reported by Whipple and Webber.⁶

CONGENITAL UMBILICAL HERNIA: REPORT OF A CASE, AND TABLE OF CASES HITHERTO REPORTED.¹

By HOMER E. SAFFORD, Ph.B., M.D.,

of Detroit, Mich.

My attention was called to this subject by a case which occurred in the practice of Dr. Geo. E. McKean, and was operated upon by Dr. F. W. Robbins.

The child, a boy weighing about 8 pounds, had been born at 3 o'clock on the morning of July 16, 1899, and at 11 o'clock of the same day I was met by Dr. McKean at the house of the parents. The only exception to the boy's apparently perfect development was the presence in the umbilical region of a tumor of dark red or purplish color, which at its upper part took on a grayish appearance, suggestive of the tissue of the cord. The circumference of the tumor was 30 cm. and that of the pedicle, taken externally, was 19.5 cm., and the protrusion from what would have been the normal abdominal surface was between 5 and 6 cm. The walls were thin, and, except where the grayish appearance mentioned was present, there was a decided transparency and at first the coils of intestine could be seen. Later this had become clouded by the drying of the outer covering of the sac. When first the child was delivered, this outer layer was smooth and glistening like the surface of the cord itself, and the area thus left uncovered by skin, almost equal to that of the whole tumor. The skin rose perhaps 0.5 cm. upon the pedicle, and at the lower border this cutaneous margin rose to form an apron of about 3 cm. width. The attachment of the cord was somewhat toward the left of the median line, and slightly above the center. Its structures were spread out over the surface after running a little distance toward the base of the pedicle where its proper termination seemed to be sought.

The intestines, plainly visible, could be largely if not completely reduced without seriously affecting the child's breathing or circulation; but underneath the upper grayish portion of the sac the character of the contents was less easily determined and reduction was impossible. This portion was presumably liver, and so it proved on subsequent section of the sac.

In the afternoon of the same day Dr. Robbins saw the case, and the conditions were recognized as presenting little or no hope for the reduction of the hernia, if, indeed, there were any for saving the life of the child, under expectant treatment. The presence of adhesions already sufficient to prevent reduction was suggestive of peritonitis, which must follow, if it were not already present, when the outer surface of the hernia should become gangrenous, and allow the further protrusion of the peritoneum and absolute evisceration. The intraabdominal pressure, it was recognized, would be considerable when the contents of so large a sac were emptied into the cavity; but the reduction of so large a proportion of the hernial contents, and the hope that by means of the apron of skin mentioned, it would be possible to bring together the tissues so as to close over the defect when the edges should be vivified, decided the matter in favor of an attempt to perform the laparotomy. It was impossible to proceed to the operation until the following morning, and the child, when this was done, was 30 hours old. After preparation and under chloroform anesthesia, the hernia was again examined and reduction still found impossible to complete. The incision into the sac was in the median line through the lower thinner portion, the contents being found as above described. Even the stomach and spleen appeared at the hernial opening. This opening through the neck of the sac was about 4.5 by 5.5 cm., and the liver, which had filled in its upper part, making a definite estimate of its size impossible before section, was tied to the inner wall of the sac by broad adhesions. Another previously uncertain factor, the intraabdominal pressure, was the final obstacle which determined the necessity of withdrawing from the operation. So long as the external opening was left large enough even for examination, the eventration was almost uncontrollable, and it was finally decided that it would be a needless proceeding to attempt the resection, as it had

¹ Read before the Detroit Medical Society, October 31, 1900.

been planned, before suturing. The wound-edges were brought together, and an antiseptic dressing applied. The child recovered, took nourishment, and had a number of movements of the bowels before the peritonitis developed, which was the inevitable end of the picture. The outer membrane, of course, became gangrenous, but the wound itself made marked progress in the matter of granulation in the 4 days before death. No autopsy was obtained.

It was not possible to determine any other case of arrested development in the parents or relatives. The mother, aged 26, was a primipara and had had a favorable term of pregnancy with no unusual disturbance, physical or mental. Syphilis was not an element in the case. It is, perhaps, worth noting that, on April 12, 1900, after three weeks of albuminuria, rapid pulse, and marked weakness, the mother bore her second child dead, at seven months.

In general this class of cases has presented a prospect anything but favorable to the practitioner and even to the skilled surgeon under whose observation it has come. Up to the coming of antiseptic practice there was little to do but wait and hope. The expectant treatment had, with a few exceptions, been the only method adopted up to 1882; aside from this the most common being some manner of ligature applied to the sac after reduction, although two or three cases of successful laparotomy followed by suturing had been recorded before this date.

Lindfors, whose table of cases reported as cured previous to 1882 (Part I of the writer's table), is accepted as authoritative, includes 34 such cures. Of these cases he cites two as having had the radical operation, strictly speaking. They were Bérard's case, about 1836 (No. 9), and that known as the Ferrara case (No. 13), imperfectly reported but briefly referred to by Cruveilhier. One other, that of Treves (No. 35 of the writer's table), is mentioned by Lindfors but not included in his table because the child died shortly after what Treves claimed was a really successful treatment. The last case (No. 36) is one to which Treves refers in the report of his own case and there seems to be no reason why it, at least, should not be included. Lindfors himself probably did the first successful operation by laparotomy and suturing under antiseptic conditions; and so he believed that a new era in treatment and a new series of cases should be considered as beginning with his own. His first table takes account only of those cases reported cured up to the time he began his work, and the results he found may be briefly summarized as follows:

Cases of successful treatment.....	34
Cases under purely expectant treatment.....	22
Cases treated by simple circular ligature of the sac after reduction.....	6
Cases with simple ligature combined with a purse- string suture (No. 5).....	1
Cases with simple ligature after opening the sac to separate adhesions of the liver (No. 19).....	1
Cases with percutaneous ligature (Nos. 33 and 34)	2
Cases with laparotomy, freshening of wound- edges, and suturing (Nos. 9 and 13).....	2

The expectant treatment in this earlier period consisted of some form of protective dressing to aid primarily in the reduction and support of the tumor, and further, it was the aim to prevent the gangrene of the outer membrane and the mucous tissue before the granulations had enclosed the underlying peritoneum. In more recent years some few cases have still to be left to this treatment, and in the light of a more careful aseptic technic such cases should not be considered destitute of hope with respect to life. As regards the ultimate perfect cure of the hernia, of course less can be expected. It is to be the aim,

in this treatment, to avoid irritation at all hazards. Measures that cause a too hasty desiccation, as well as anything that would tend to macerate the coverings, are to be avoided. The normal mummification of the cord should be considered the due course of this process, and a strict asepsis is to be maintained.

Operative treatment may be said to have been begun when the reduction of the hernial contents was followed by a simple circular ligature, which aimed to cause sufficient adhesion of the neck of the sac to aid in bridging across the defect. Another step was taken when a purse-string suture was thrown around the neck of the hernia, and, finally, this method reached its climax in the so-called percutaneous ligature, usually described as Breus' operation. In this measure the particular added feature was a clamp provisionally applied to the pedicle after reduction, which should maintain the latter, while two needles upon the same thread were passed about 1 cm. apart immediately below it. The thread or ligature was then cut at each of the needles and thus three separate ligatures formed, and these each contained, when tied, its own portion of the neck of the sac. Breus claimed especial advantage for his operation in only a limited class of cases, viz., those where not too wide a defect existed in the abdominal wall, and where the skin rose far enough upon the tumor to furnish a cutaneous ring upon which to apply the clamp and through which to pass the ligatures. It could be applied only in cases, too, where the contents of the sac were completely reducible, or exceptionally where a small loop of intestine remained adherent which could be separated and reduced by incision of the sac after the clamp was applied. In one of Breus' cases he found a persistent adherent diverticulum of Meckel which he included in the ligature and carefully tied with the other tissues. This author claims for his operation a very satisfactory manner of healing and a firm cicatrix, but the critics have largely admitted the claim that the method holds open the possibility of setting up a peritonitis by taking up small portions of only partially reduced intestine. Fleischmann, from Breisky's clinic in Prague, reported that the vermiform appendix was caught upon the needle. Breus in reply says "this rare misfortune is not difficult to avoid if the sac is opened and examined" after the clamp is applied and before the ligatures are passed. He certainly accomplished two very satisfactory results and in another the wound conditions were essentially perfect. A practical point he offers in favor of the method is the possibility of carrying it out on short notice, under conditions unfavorable for elaborate preparation and the skilled assistance needed for laparotomy and suturing. It is needless to add that this operation must be carried out under conditions as rigidly aseptic as though the greater surface were exposed. It is not maintained as the perfect operation, but historically it is interesting, and, practically, may be useful.

In Bérard's case we see a foreshadowing of the practice of Lindfors and that which is considered proper for all favorable cases today. That his case recovered may be due to an unusual tolerance on the part of his patient; but to Bérard must be given the credit for approaching in a rational manner the treatment of this condition at a time when the weight of opinion was against him. Oken, in 1810, is said to have suggested the idea of radical operation, but no claim is made that he knew of any case where it had been successfully performed. Sömering in 1811, Malgaigne in 1840, and, even as late as 1880, König and Vogel are quoted as

RECORDED CASES OF HERNIA FUNICULI UMBILICALIS.

I.—LINFORDS' TABLE OF CASES REPORTED CURED, PREVIOUS TO 1882. (*Volkmann's Sammlung Klinischer Vorträge, N. F., No. 10, 1882.*)

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
1	Storch.	Therap. und prakt. Abhandlungen von Kindkrht., Eisenach, 1751.	Male.	Large as a medium-sized apple. Cord attachment, central.	Repression and compressing bandage.	Healed after 6 weeks.	The meconium could be seen through the coverings in the intestine. Compression maintained by means of strips of plaster in form of a cross. Child was living 14 years later.
2	Lobstein.	Buchholz: Dissertation de hepatomphalocele, 1768.	Male.	Hernia, 3 inches in diameter. Contained liver.	Simple protective dressing.	Healed after 4 weeks.	On the third day the outer membrane was cast off. Child died some time later of whooping-cough.
3	Herold.	Starke: Archiv für Geburtshilfe, Jena, 1787.	Male.	As large as a coffee-cup. Cord attached at the lower segment.	Simple protective dressing.	Healed, but time not given.	Dressing at first consisted of lead-water compresses; later, of linen covered with cerate.
4	Hey.	Pract. Observations in Surg., London, 1801.	Male.	As large as a hen's egg.	Compressing bandage.	Healing in 15 days. Cord came away on eighth.	Dressing consisted of several star-shaped pieces of plaster laid one upon another, and over this a bandage with a crescent-like filling in one end.
5	Hamilton, Cooper.	Case XV in Cooper's Anat. and Surgical Treatment of Inguinal and Umbilical Hernia, Vol. II.	Female.	Coils of intestine.	Ligature and suturæ circumvolutæ.	Healed after some days.	After hernia was reduced and sac ligated, edges of hernial opening were brought together by transfexion with silver pins, around which thin strips of adhesive plaster were wound. Case sometimes cited under name of A. Cooper.
6	Schneider.	Allgemeine med. Annalen, Altenburg, 1819.	...	Size of a closed fist.	Reduction and compressing bandage.	Healed after 11 days.	Several compresses over one another and bandage applied over all.
7	Ribke.	Rust's Magazin f. die gesamte Heilkunde, 1820.	Female.	Hernia, 2 inches in diameter. Motion of intestines visible through membranes.	Simple protective dressing.	Healed after 4 weeks. On second day, opacity of membranes; on third, beginning desquamation. Underlying granulations.	Reduction not attempted. Sought to protect hernia from all pressure. Cloth wound around it, and a loosely-applied bandage over it. Child died a year later of "dentition fever," and autopsy showed a separation of $2\frac{1}{4}$ inches between the musculi recti
8	Müller.	Rust's Magazin, 1823.	...	As large as a closed fist and with narrow neck.	Reduction and ligature.	Healed after 3 weeks.	
9	Bérard.	Schmidt's Jahrbücher, 1836; and Jour. des connaissances medic. et dict. de médecine, 1840.	...	Adhesion of intestine to sac.	Radical operation.	...	Sac incised. Adhesion separated. Bowel reduced. Skin-edges approximated with sutures.
10	P. G. Cederskjöld.	Förlossningskonst, Stockholm 1839, Vol. III, p. 162.	Male.	Hernia, 1 inch in diameter.	Ligature.	Healed after 3 weeks.	
11	Bal (in Tiel, Holland).	Archiv. gen. d. med. Also, Mag. d. ausl. Litter. d. ges. Heilkunde, Hamburg, 1830.	Female.	Largest known umbilical cord hernia, 7 inches (rhenish) in diameter. Contained "most of the abdominal viscera."	Reduction, ligature, and protective dressing.	Healed in 10 weeks.	When the ligature was applied, the area uncovered by skin measured 2 inches in diameter. Covered with lint dipped in red wine and over this a bandage. On third day, when the swelling had relaxed, a new ligature above the first was applied and the skin drawn together with adhesive plaster. On fifth day, latter was renewed. Then the outer membrane, at the edge, began to desquamate. Some pus came forth and granulations showed beneath it. Later, when more of the membrane was shed and the purulent discharge was very free, the dressing was changed to compresses, soaked in a decoction of willow-bark with alum.
12	Panarelli.	Cruveilhier: In Cooper's "Pathologie generale," Vol. I, p. 604, 1849.	...	When reduction was effected, child had an attack of syncope.	Simple protective dressing.	Healing, but time not given.	Over the hernia the omentum of an animal just killed was laid. Sometimes referred to as Cruveilhier's case.
13	House-Surgeon in Hospital in Ferrara.	Referred to by Cruveilhier in "Pathologie generale."	Radical operation.	Healing, but time not given.	First case reported where wound-edges were freshened before suturing. This treatment is not countenanced by Cruveilhier.
14	Reguin.	Gaz. med. de Paris, October, 1832.	Male.	As large as a closed fist. Attachment of cord, central.	Simple protective dressing.	Healed after more than 50 days.	After hernia was reduced, child became quiet. Dressing consisted of cerate plaster spread with almond-oil, and over this a flannel bandage.
15	Stoltz.	Bulletin de Therapeutique, T. 53.	Male.	Small hernia, projecting 4 cm. Diameter, 7 mm.	Simple protective dressing.	On thirteenth day, cord fell away, together with the outer membrane. Layer of granulations beneath healing on fourth day.	Child showed no discomfort from pressure on sac. Immediately after healing, bilateral inguinal hernia appeared. Child died 3 months later; cause unknown.
16	Goyrand.	Annales de chirurg., 1844.	Simple protective dressing.	Healing.	Child lived $2\frac{1}{4}$ months, and wound nearly healed, when death occurred from intercurrent affection.
17	Getto.	Orlac refers to this case as occurring in 1860. Also, Linford, in Centralbl. f. Gyn., 1884, No. 30.	Male.	As large as half an apple.	Simple protective dressing.	Healing after 7 weeks. Was seen again after 17 years.	Dyspnea caused by pressure upon the sac. Also, in nursing. Dressing. Pieces of linen covered with oil, and over this a bandage.
18	Thelu.	Jour. de Chirurg. de Malgaigne, 1864.	Female.	Circumference of hernia, 24 cm. Opening 3 cm in diameter.	Compressing bandage.	Healing in 27 days.	On the tenth day convulsions, which soon ceased.
19	Pochhammer.	Casper's Wochenschrift, 1846.	...	Large as a goose's egg. Liver in the hernia and adherent.	Radical operation. Incision of sac. Separation of liver. Reduction. Ligature.	Healing, but time not stated.	Ceatrix, size of a dollar and visible so that a protrusion of size of fist remained.
20	Herrgott.	In Debout's Memoire, communicated in 1860. (From year 1846.)	...	As large as half an ordinary apple. Cord attached at the right side.	Simple protective dressing.	Healing, but time not stated.	Often cited as Deibert's case.

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
21	Reutermann.	Hygiea, 1861, p. 747.	Male.	As large as a child's head. Contained intestines and part of liver. Skin spread upward 1 inch on the hernia.	Reduction and ligature.	Healing.	Operation 14 hours after birth.
22	Margariteau.	First in communication to Bulletin de Therapeutique, 1855. (From year 1847.)	Male.	Size of large hen's egg.	Simple protective dressing.	On eighteenth day, cord came away. Recovery after somewhat more than one month.	Dressing: Cerate-lint and bandage. Patient was seen again after 13 years.
23	Kraemer.	Zeitschrift f. ration. Med., 1853.	Female	As large as a closed fist. Liver adherent in the sac. Cord attached below and at left.	Compressing bandage.	On seventh day, cord came away. On the sixteenth, healed.	Dressing: Long adhesive plaster strips over a piece of linen smeared with cerate. Died of eclampsia 3 weeks after healing. Autopsy showed 2½ inches separation between musculi recti.
24	Thudichum.	Vierteljahrsschrift f. prakt. Heilkunde, 1853.	Male.	Circumference, 16 cm.; 2½ cm. high.	Reduction and ligature.	Healing in 36 days.	
25	Rose.	Monatsschrift f. Geburtskunde, 1868. Lindfors: Centrbl. f. Gyn., 1881, No. 30.	As large as a child's head. Liver in sac. Irreducible on account of adhesions.	Simple protective dressing.	Vain attempt at reduction by another surgeon. Afterward, again expectant treatment.	On sixteenth day wound cleared up, and in twelfth week was healed. Dressing: Zinc ointment and bandage; afterward, solution of silver nitrate. Child died of diarrhea 3 weeks after healing. Autopsy: Separation of almost 6 cm. between musculi recti. Cicatrix 2½ cm. broad from the peritoneum, to which the liver also was firmly adherent, it was not to be separated.
26	Guersant.	Mentioned by Orliac, 1877. (From year 1860.)	Male.	As large as half an apple. Opening measured 6 cm.	Simple protective dressing.	On ninth day, cord and outer membrane came away.	Cerate-linen and bandage.
27	Raymondaud.	Published in "Bulletin de la Soc. de Med. de la Haute-vienne," 1868. (From year 1861.)	Female	Stellate. Circumference, 24 cm. Opening, 3 cm. Cord inserted centrally.	Compressing bandage.	Healed on thirty-ninth day.	Dressing: Cotton tampon and disk of cork with bandage. After one day, pressure symptoms compelled the removal of the cork disk. No bathing. On sixth day, the gangrenous remains of the outer membrane were removed and fresh granulations found covering the inner one.
28	Cooper, Forster.	In Holmes' Surgical Diseases of Children, 1869.	Rather large hernia.	Simple protective dressing.	Healed.	
29	Chamorro.	Amfitreato anatomico Español, 1875.	Simple protective dressing.	On sixth day, cord came away. Healing, but time not stated.	The course was "interrupted by an attempt at operation." Local phlebitis. Fecal vomiting. Soor. Improvement and recovery.
30	B. Angers.	First published in Orliac's Thesis, 1877. Also, Lindfors' article in Centrbl. f. Gyn., 1884, No. 30.	Female	As large as an orange. Liver in the sac.	Simple protective dressing.	On sixteenth day, cord came away. Healing only after 11 weeks.	Compresses with "vin aromatique" and bandage.
31	Fear.	Brit. Med. Jour., 1878.	Ligature.	Healing, but time not stated.	
32	Th. Bryant.	Pract. of Surg., third edition, 1879.	Large hernia, containing liver.	Simple protective dressing.	Healed.	The serosa granulated, formed a cicatrix, and thus gradually pressed the hernial contents back.
33	Th. Bryant.	Pract. of Surg., 1879. (Operated upon July, 1876.)	Male.	Large as a hen's egg. Contained cecum.	Reduction and percutaneous ligature.	Healed.	The boy was living 2 years later.
34	C. Breus.	Wiener med. Wochenschrift, 1881. Also, Samml. u. klin. Vorträge, 1893, No. 77.	Female	Size of a hen's egg. Contained only coils of intestine. Opening, 3 cm. in diameter.	Reduction and percutaneous ligature.	Healed.	Operation, 20 hours after birth. After reduction, temporary closing of hernial opening by means of forceps, followed by percutaneous ligature and removal of sac with Paquin's thermocautery. Antiseptic dressing.
35	Treves.	London Lancet, 1881, I, 323 [Mentioned by Lindfors, but not included in his table as cured.]	Male.	In base of cord, swelling size of bantam's egg. Almost absolutely irreducible. Opening, size of adult thumb. Contents 2 inches of ileum, whole of cecum, and vermiform appendix. Cecum largely adherent. Firmly strangulated.	Radical operation. At first incision along the whole length of tumor in median line. Abdominal opening enlarged. Gas in intestine relieved by puncture with hypodermic needle. Reduction. Harelip-plins, including peritoneum. Silk, through skin only.	Recovery in 7 days, wound healed, but died after 3 weeks from diarrhea, followed by convulsions. Had left hospital cured.	Seven day after birth. Operation refused, but granted next day, when peritonitis and exhaustion were advanced. No movement of bowels. Vomiting. Operation under chloroform, 60 hours after birth. Improvement began within 12 hours. Copious movement of bowels. Took nourishment next day. No vomiting. Pils removed at 36 hours. Wound supported by strapping. Examination, day before death, showed scar firm and well healed, appearance like normal umbilicus. Operation was without antiseptic precautions.
36	Visik (Malaga).	Idem, 1873, I, 829. [Not mentioned by Lindfors.]	Size of hen's egg. Very thin and transparent. Opening, size of a pencil. When seen, sac was ruptured, and evisceration included cecum and appendix, ascending and transverse colon and greater part of small intestine.	Reduction, with difficulty. Skin-edges secured by temporary clamp and sutured with wire.	Wound closed top day. At end of 5 weeks, patient strong and healthy.	Wound healed by granulation, which for a time was excessive, and the fungous growth was treated.

II.—LINDFORS' TABLE OF CASES OF HERNIA FUNICULI UMBILICALIS, 1882-1891. *Uppsala's Stenbäck klin. Vorträge, N. F., No. 53, 1891.*

S.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
1	A. O. Lindfors.	Hygiea, Stockholm, Jan., 1882; Nord. Med. Archiv, IV, 1883; Centrbl. für Chirurgie, 1882, No. 49; Centrbl. für Gynäk., 1884, No. 30; Centrbl. für Gynäk., 1889, No. 28; Samml. klin. Vorträge, 1893, N. F., No. 63.	Male.	Hernia, size of child's head. Hernial opening, 5 cm. in diameter. Insertion of cord below and at left. Contents, intestine.	Laparotomy and suturing, antiseptic. Simple radical operation.	Progressive healing. Superficial sutures removed, seventh day. Deep, tenth day. Firm, deep union. Superficial suppuration. Union complete twenty-eighth day.	Under anesthesia and under thymol spray. Reduction. Excision of sac and cord. Sutures—one row deep, one superficial.
2	Krukenberg.	Archiv für Gynäk., 1882, II, XV; Centrbl. für Gynäk., 1883, No. 1.	Liver and omentum adherent in the sac. Hernial opening, 3.5 cm. in diameter.	Laparotomy and suturing. Simple radical operation. Antiseptic.	Healed in 30 days.	Incision of sac. Adhesions broken. Reduction. Skin-edges freshened. Compress. Salicylic acid.
3	Ronaldson.	Tr. Edin. Obst. Soc., 1882-1883, VIII, 101.	Male.	Large hernia, with adhesions.	Radical operation.	Cure.	Incision of sac. Adhesions separated. Reduction. Suture.
4	Breisky, Fleischmann.	Prager med. Wochenschrift, 1882; Centrbl. für Gynäk., 1883.	Male.	Size of walnut. Only intestines.	Percutaneous ligature; excision of sac; cautery.	Death.	Vermiform appendix was caught in the ligature and tied.
5	Pagenstecher.	Bulletin gen. de Therapeutique, 1883; Virchow-Hirsch Jahrbücher, 1883.	Strangulated.	Radical operation. Antiseptic.	Cure.	Incision of ring. Reduction. Suture of wound.
6	Felsenreich.	Wiener med. Presse, 1883; Lindfors, Centrbl. f. Gyn., 1889, No. 28.	Size of lemon. Skin defect, 8.4 cm. Contents, intestines and edge of liver.	Radical operation. Excision of sac. Skin-edges vivified. Sutures. Iodoform compresses.	Cure.	Operation at age of 2 days. Primary healing.
7	Goodlee.	Med. Times and Gaz., 1883.	Contents, small intestine and cecum.	Radical operation. Reduction. Freshening. Sutures.	Died, 3 days after operation.	Child was first seen at 2 days old. For 14 days, expectant treatment. Already peritonitis before operation. Reduction difficult. Cecum adherent.
8	Soudèn.	Hygiea, 1883, 146; Lindfors, Centrbl. für Gyn., 1889, No. 28.	Large as a common potato. Intestine only. Cord, central. Hernial opening, 1 cm. in diameter.	Ligature. Bandage with gentle compression.	Cure (time not stated). Cord came away on tenth day.	After reduction, the empty sac was closely wound with strips of adhesive plaster. Over this a gently-compressing bandage.
9	C. W. Robinson.	Lancet, 1883; Virchow-Hirsch Jahrbücher, 1883.	Male.	Intestines only. No adhesions.	Radical operation.	Death after 2 hours.	Operated upon the day after birth.
10	Harries.	Lancet, 1886, II, 773.	Size of hen's egg. Adhesions.	Radical operation. Sutures circumvoluted.	Cure.	Child only a few hours old at time of operation.
11	S. v. Hofsten.	Hygiea, 1886.	Female	Size of goose's egg. Intestines and liver.	Simple protective bandage.	Death.	Ten days old when first seen. Died next day, of peritonitis.
12	Caldwell.	Trans. Gyn. Soc. of Chicago, 1886; Centrbl. für Gynäk., 1887, No. 2.	Circumference of hernia, 10 inches.	Herniotomy. Reduction. Freshening. Sutures.	Cure.	On sixth day, fecal discharge from wound. Later, fistula healed.
13	Olshausen.	Archiv für Gynäk., 1887, XXIX.	Female	Hernial opening 4.5 cm. wide.	Modified radical operation. Extraperitoneal.	Cure.	Amnion and Wharton's jelly removed, but peritoneum left intact. Incision through skin alongside hernial opening. Sutured over the infolded peritoneum. Hemorrhage. Healing, but not primary. Granulation filled in lower third of wound.
14	Fleischmann.	Prager med. Wochenschr., 1887; Centrbl. für Gynäk., 1887.	Female	Large.	Simple protective bandage.	Cure.	The defect in the abdominal wall was too great to bring the sutures together. Dressing of cotton covered with boric acid and vaselin.
15	Reuter.	Geburtsh. Gesellschaft von Hamburg; Centrbl. für Gynäk., 1887.	Male.	Abdominal opening 4.5 cm. Already peritonitis.	Herniotomy. Reduction. Separation of adherent liver. Skin-edges freshened. Sutures.	Cure.
16	Stypinski.	Gaz. lekaraska, Bd. VI, 8; Centrbl. für Gynäk., 1887, No. 13.	Male.	Circumference, 12 inches. Longitudinal diameter, 5 inches.	Compression and bandage.	Death, in 4 weeks.	Heart was visible and palpable among intestines in the sac. Defect too great for operation.
17	Robertson.	Glasgow Med. Jour., 1887; Centrbl. für Gyn., 1887, No. 47.	Large as a child's head. Hernial opening size of a dollar.	Simple protective bandage.	Death, on ninth day.	Great dilation of duodenum. Small intestine opening directly out at anus. Colon wanting.
18	Piperno.	Sperimentale, Dec., 1887; Centrbl. für Gynäk., 1888, No. 28.	Male.	Defect, 5 cm. long.	Radical operation. Reduction, difficult. Freshening. Sutures.	Death, on second day.	Operation without preparation and without skilled assistance, in unheated room, in farm-house. Directly after suturing, bowels underwent eversion.
19	Dunlap.	Jour. American Med. Assoc., 1888; Centrbl. für Gynäk., 1888, No. 43.	Very large. Intestines in the sac.	Radical operation. Freshening. Sutures.	Cure.	Child an hour old. Healing by primary union.
20	Dohrn, Eckerlein.	Zeitschr. für Geburtsh. und Gynäk., 1888, XV, 2.	Female	Size of hen's egg. Patient had six fingers on each hand.	Modified radical operation. Extraperitoneal.	Cure.	Five hours after birth, operation according to Olshausen's method. Carbolic acid used during operation. Healing, secondary. Afterward, protrusion of umbilicus. Died after 6 weeks, from pneumonia.
21	Phenomenoff, Stolypinsky.	Diary of Kazan (Russia) Med Soc., VIII, 1888; Centrbl. für Gynäk., 1889, No. 11; Annals of Surgery, 1888.	Size of goose's egg	Radical operation. Freshening. Sutures.	Cure.	One hour after birth, operation under chloroform. Only boiled water, by way of prevention. Hernial opening enlarged. Considerable hemorrhage. A portion of the intestine adhered so firmly that a part of the peritoneum of the sac was dropped into abdominal cavity with hernia. Primary union.
	Auvard.	Revue de Gynecol., Paris, 1888; Centrbl. für Gynäk., 1888, No. 28.	Male.	Fecal fistula.	Simple protective bandage.	Death.

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
23	Barton.	Medical News, 1889.	...	Size of closed fist; 2 inches in diameter.	Radical operation.	Cure.	Operation 23 hours after birth. Already peritonitis.
24	Theims.	Frauenarzt, Berlin, 1889, Vol. X, 277.	...	Large and adherent.	Radical operation.	Cure.	
25	Macdonald.	Ann. Jour. Obst., 1890.	Female	Size of an orange.	Radical operation. Suture circumvolutae.	Cure.	Child very strong 2 months later.
26	Baum, Colla.	Centrbl. für Gynäk., 1890, No. 21.	Female	Pear-shaped tumor with pedicle. Contents, only liver. Strangulated. Irreducible.	Radical operation. Reduction. Suture.	Death, 7 hours later.	Operation 15 hours after birth. Chloroform anesthesia. Salivary and antiseptic. Adhesions of liver. Hernia opening scarcely the size of little finger. Opened upward.
27	Lauderer.	Centrbl. für Gynäk., 1890, No. 31.	Male.	Contents: Small intestine, part of stomach, transverse colon, and omentum. Adhesions to stomach.	Radical operation.	Cure.	Anesthesia. Operation 15 hours after birth.
28	Larabrie.	Archiv. gen. de med., 1891; Centrbl. für Chirurgie, 1891, No. 52.	Male.	Hernia sac ruptured. Contents, intestine.	Radical operation.	Cure.	Relief of constriction, upward. Adhesions dissolved. Reduction. Excision of sac. Sutures. Operation 7 hours after birth.
29	Salmon.	Gaz. des Hôpit., 1891, No. 132.	Male.	Size of an orange. Contents: Bloody ascitic fluid, greater part of liver, and cord of omentum size of little finger.	Simple incision of sac. Freshening of wound-edges. Deep and superficial sutures.	Cure, after 14 days.	Cord of omentum tied off and excised. Reduction of liver. Chloroform anesthesia. Bore a gauze dressing. Two sutures cut through, and suppurred a little.
30	Hinkinson.	New York Med. Jour., 1891; Centrbl. für Chirurg., 1892, No. 8.	...	Length of hernia, 12 cm. width, 6 cm. Contents, part of liver and small intestine.	Simple incision of sac. Reduction. Sutures.	Cure.	Child recovered in spite of the fact that, when the wound was dressed the first time, the sutures came out. Repeated under anesthesia.
31	Runge.	Archiv für Gynäkologie, 1891; Centrbl. für Gyn., 1892.	Female	Size of lemon. Liver and intestines.	Simple incision of sac. Reduction. Sutures.	Healed in 20 days.	Broad adhesions with liver. Silver sutures.

III.—CASES TABULATED BY BERGER, OCCURRING UP TO 1893. (*Revue de Chirurgie, October, 1893.*)

32	D'Arcy, Power.	Trans. Path. Soc. of London, 1888, XXXIX, 108.	...	Transparent sac. Contents, a foot of small intestine.	Incision of sac. Reduction. Sutures.	Death, after 3 days.	Peritonitis. Reduction impossible without operation.
33	Jean (de Maubeuge).	Routier: Bulletin et Mem. de la Soc. de Chirurgie, 1891, N. S., XVII, 17.	...	Rupture of sac. Protrusion of ileum and cecum.	Reduction. Expectant treatment.	Cure.	Vomiting, fecal, due to chilling.
34	Manoury (Chartres).	Salmon: Gaz. des Hôpitaux, 1891, No. 132.	Male.	Size of mandarin. Transparent at base. Contents: The liver, a band of omentum, and some ascitic fluid.	Radical operation. Liver red. and lig. and superficial sutures. Omentum excised.	Cure, after 5 days.	No antiseptic precaution taken during 24 hours after birth. Operation between twenty-fourth and thirtieth hour. Antiseptic. Two sutures cut and suppurred slightly.
35	Kaltenbach.	O. Patz: Inaugural Dissertation, Halle, 1891, p. 32.	Male.	Size of closed fist. With pedicle. Intestinal adhesions.	Radical operation. Incision of sac. Excision. Separation of adhesions. Reduction. Suture.	Cure.	Operation, 11 hours after birth. Anesthesia, chloroform.
36	W. Hogue (Charleston).	Henry Marcy: Anatom. and Surg. Treatment of Hernia, New York, 1892, p. 193.	Male.	Opening, 2 inches. Tumor, descending to pubis.	Expectant. Support by adhesive bandage.	Cure, after 6 weeks.	
37	Henry O. Marcy.	Idem, p. 194.	Male.	Tumor, radius 2 inches. Contents: Part of liver and spleen.	Olshausen's operation.	Cure.	Operation 2 days after birth. Chloroform. Partial failure of union and suppuration. Small protuberance when child cries.
38	Angelo Nannotti.	Morgagni, 1892, XXXIV, 515.	Male.	Size of head of fetus at term. Sac torn opening, 3 cm. in diameter. Contents: Large and small intestine.	Hermolacramotomy. Incision in linea alba. Excision of sac. Reduction. Deep and superficial sutures.	Cure, after 10 days.	Operation immediately after birth.
39	Samuel C. Benedict.	Med. Record, N. Y., 1892, XLI, 262.	...	Contents: Spleen, part of liver, and intestines.	Raised amnion and Wharton's jelly, saving peritonitis. Free skin from both sides and draw over opening.	Cure.	Chloroform. Operation 48 hours after birth. Dependent on sutures and ligatures. Wound dressed with gauze. Peritonitis of part of wound. Wound dressing was removed. Small protuberance remained when child cried.
40	Carl Breus.	Sammlung klin. Vorträge, 1893, No. 77, p. 726.	...	Size of an orange. Sac. With difficulty reduced. Opening a good 7 cm. in diameter. Contents: Intestine and liver.	Percutaneous ligature. Very difficult. Impossible to satisfactorily apply the forceps to walls of the opening.	Death.	Operation under chloroform 8 hours after birth. Wound extensively opened with scissors. Not from peritonitis. Caustic put used as in Breus's first case—Table I, No. 4.
41	Carl Breus.	Idem, p. 727.	...	Protrusion 8 cm. With redness. Incompletely reduced. When touched a diver tingling of Meckel.	Percutaneous ligature. Excision of the diverticulum taken up by the ligature.	Cure, after 14 days.	Operation under chloroform 7 hours after birth. No distension. Chloroform norm and smooth after 9 months.

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
42	P. Berger.	Revue de Chirurgie, 1893, p. 798.	Female	Size of hen's egg. Contents: Small intestine, cecum, and with transverse colon adherent.	Hernio-laparotomy. Incision in linea alba. Reduction. Sutured in three layers.	Cure, after 10 days.	Operation under chloroform, 28 hours after birth. Iodoform dressing had been used. Primary union.
43	P. Berger.	Revue de Chirurgie, 1893, p. 802.	Female	Size of large walnut. Contained small intestine and adherent cecum.	Operation as for No. 42.	Cure.	Operation under chloroform, 3 days after birth. No antiseptic preparation had been taken meantime. Peritonitis had already begun before operation. Cure, 18 days after removal of sutures. Union by first intention.

IV.—REMAINING CASES IN HALLET'S TABLE. (*Revue de Gynécologie, June, 1900.*)

44	Bruss	Centbl. für Gynäk., 1884, No. 30, p. 478; Thèse de Vienne.	Male.	Size of lemon. Contents: Intestine and part of liver. Abdominal opening, 8 cm. by 4 cm. Membranes very tense.	Radical operation.	Cure.	Operation 7 hours after birth. Primary healing. Sutures removed, ninth day.
45	Gluck.	Berliner klin. Wochenschr., Jan. 19, 1885.	Signs of peritonitis. Strangulation, due to an accessory mesenteric fold bound to diverticulum of Meckel and passing over intestine.	Radical operation. Resection of diverticulum and of the mesenteric fold.	Death.	Child born at 7 months. Died in 30 hours, of peritonitis.
46	Duchamp.	Loire Medical, Nov. 17, 1887; Thèse de Vienne.	Size of walnut. Thin, transparent sac. Reduction easy. Just as operation was to begin, sac suddenly burst and intestine poured out en masse.	Diverticulum tied as far as possible from intestine with silk thread, to hold it outside the ring. Its middle part was then fixed at the level of the umbilical ring.	Death.	When sac burst, small intestine appeared and cecum, with its appendix, the sigmoid flexure, and a diverticulum of Meckel, of 2 cm. in length, adherent to hernial sac by its extremity.
47	Klaussner.	Münch. med. Wochenschrift, 1889, No. 3.	Male.	Size of an apple. Irreducible. Short pedicle of 1 cm. thickness. Hernia 5 cm. in diameter. Easily strangulated. Tumor tense.	Radical operation. Coils of intestine, inflamed and covered with exudate.	Cure.	No anesthetic. Age, 1 day. Died later, of diarrhea. Postmortem, umbilicus closed. No adhesions to side of intestine.
48	Péan.	Cliniques Chirurgicales, VIII, 717.	Size of head of child 2 months old. Coverings adherent to liver and intestine.	Radical operation. Resection of suspending ligament of liver. Separation of large and small intestine, and afterward a removal by piecemeal of Wharton's jelly. Reduction difficult.	Result unknown, but it does not seem that a favorable result could have followed.	Anesthesia difficult. Child 6 hours old and very much depressed after operation.
49	Rosenblum.	Altona, 1891, p. 8. (Quoted by Cahier.)	Umbilical hernia with persistent omphalo-mesenteric duct.	Radical operation.	Cure.	
50	Bordeau.	Limousin Médicale, 1891, p. 148; Thèse de Vienne.	Male.	Size of an orange. With pedicle. Partly reducible. Contents: Part of small intestine and cecum with appendix closely adherent to the sac.	Radical operation. Cleansing with bichlorid solution. Intestines came out en masse and more extensive laparotomy necessary to reduce them.	Death.	Child 2 days old. Already peritonitis at operation. Its extension caused death 18 hours after operation.
51	Vanderloel.	Jour. de médecine de Bruxelles, 1892.	Size of fist. Contents: Liver and other viscera.	Reduction. Suture of the ring with catgut.	Cure.	Operation some hours after birth.
52	Warren.	Lancet, 1893, II, 1332.	Large. Opaque. Diameter, 6.5 cm. Contained entire liver.	Radical operation.	Cure.	Operation when 34 hours old. Anesthetic, ether.
53	Warren.	Idem.	Pear-shaped. Length, 7 inches. Contained nearly all the small intestine.	Radical operation.	Cure.	Child at first very much depressed, but ultimately recovered.
54	Dolinski.	Centbl. für Gynäk., 1893, No. 40.	Size of an apple.	Radical operation.	Cure.	
55	L. Hecht.	Münch. med. Wochenschr., 1894, No. 51, p. 1687.	Of small size. Membranes mammated.	Antiseptic dressing.	Cure.	Child first seen at 3 days of age. Cure by gradulation.
56	Gener.	Centbl. für Gynäk., 1894, No. 42.	Size of an apple.	Antiseptic dressing.	Cure, in 4 weeks.	Abdominal walls grew together. Umbilical ring had diameter of a lead-pencil.
57	Bardeleben, Rettig.	Rettig: Inaugural Dissert., Berlin, 1894.	Size of walnut. Contents: Appendix, large part of small intestine and its mesentery. Partly irreducible.	Radical operation.	Death.	Age at operation, 2 days. Died 5 hours afterward. Operation without anesthesia and lasted one-half hour. Postmortem: Adhesive peritonitis and punctiform hemorrhagic foci in the peritoneum.
58	Poppelmann.	Inaugural Dissert., Marburg, 1894.	Sutures through skin and amnion.	Cure.	

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
59	Timmer.	Genotschler bowerd. d. Natur. gener., 1896.	...	Loops of intestine and adherent liver in the sac.	Radical operation.	Cure.	Age, 17 hours.
60	Arndt.	Archiv für Gynäk., 1896.	...	Size of small walnut.	Radical operation.	Death.	Protrusion of small intestine outside of hernia. Age, 16 hours.
61	Arndt.	Centrbl. für Gynäk., 1896, No. 24.	Female	Umbilical hernia with hernia of heart. Absence of anterior part of diaphragm at level of sternum. Liver and intestines.	Radical operation.	Death.	Age at operation, 7 hours. Death from compression of the heart.
62	James Harvey, Raymond.	Medical Record, September 19, 1896, p. 425.	...	Hernia, large and firm. Contained entire liver. Absolutely irreducible.	Radical operation.	Death.	Died shortly after operation. Child weighed 2 k. 41, and the liver 113 g.
63	N. P. Marjantschik.	Annalen der Russ. Chirurgie, 1896, Hft. 3. Centrbl. für Chirurgie, 1896, No. 42; Centrbl. für Gynäk., 1896, No. 13.	Female	Size of lemon. Amnion dry and friable, and partly broken open. In places peritoneum also torn.	Excision of sac. Wound-edges freshened. Sutures through the whole wall.	Death on 5th day.	After operation, cognac by mouth and rectum to overcome depression. Postoperative peritonitis and gastritis, the latter due to cognac; fetal spleen, left lobe of liver twice the size of the right, and a tongue-shaped lobe behind.
64	Buist.	Brit. Med. Journal, 1896.	...	Opening 6 cm. in diameter. Cecum and liver adherent.	Radical operation.	Death.	Age 7 days. Died the following day. From birth to operation a corn and dressing had been used. Part of the time a pad of cork also used.
65	O. Piering.	Prager med. Wochenschr., 1896, No. 31.	...	Walls of hernia unusually thick. Sac ruptured in labor. Eventration of large and small intestine and mesentery, except duodenum and rectum.	Radical operation.	Cure.	Laparotomy. Reduction impossible. Hernial opening would scarcely admit the little finger. Anesthetic, chloroform, well borne.
66	Knauer.	Centrbl. für Gynäk., 1897, No. 2.	Male.	Size of mandarin. Cecum and small intestine.	Radical operation.	Cure.	At first, an attempt to employ Olshausen's method, but reduction impossible, owing to adhesions.
67	Girard.	Correspond. für Schw. Aerzte, 1897, No. 13.	Male.	Size of small fist. Contents: Part of left lobe of liver, and coils of small intestine. Great part of liver visible. Solidly adherent to sac.	Radical operation.	Cure.	Age 36 hours. Liver separated only with great difficulty. Much parenchymatous hemorrhage. Died some weeks after leaving hospital. Phlegmon of scrotum.
68	Girard.	Idem, 1897, No. 13.	Female	Size of fist. Bad color and odor of envelopes. Contents: Large part of small intestine, and all of left lobe of liver.	Radical operation. Intestine reduced. Lobe of liver resected from sac. Excised gallbladder after tying cystic duct.	Death after 36 hours.	Age 2½ days. Child debilitated.
69	E. Patry.	Revue Medicale de la Suisse Romande, 1896, No. 7, p. 354.	Female	Hepatocoele.	Attempted to suture edges of resected membrane over liver when reduced, but sutures did not hold, the membrane being too friable. Vivified skin edges and sutured abdominal walls <i>en bloc</i> .	Cure completed at end of 6 months.	Age of child, some hours. After operation intense icterus for 6 days, without decoloration of stools. Child, after recovery, was robust. Hernia, size of pigeon's egg, persisted appearing only when child cried. Evident on percussion. Ring allowed passage of two fingers. Bandage maintains reduction.
70	Boise.	Am. Jour. Obst., 1897, p. 223.	...	Hernial opening nearly as large as silver dollar. Contents: Intestine. Reducible. Soft and compressible.	Radical operation. Excision of sac. Suture fascia with silk and skin with catgut.	Cure after 3 weeks.	Operation on child at age of 7 hours. Anesthesia, not profound, with chloroform.
71	Church.	N. Y. Med. Jour., Jan., 1897.	...	Contained colon. Reduction impossible.	...	Death after 36 hours.	
72	A. MacCosh.	Idem., Feb., 1897.	Male.	Size of an orange. Color, purple. Contents: Intestine. Partly irreducible.	Radical operation.	Death after 2 days.	Operation 5 days after birth. Chloroform anesthesia only at moment of reduction. Liver covered with exudate. Parenchymatous hemorrhage. Drainage of wound.
73	Rogier.	Thèse de Paris, 1898, p. 79.	Male.	Size of an orange. With pedicle. Contents: Intestine adherent. Agglutination by peritonitis.	Radical operation.	Death.	Operation second day. Died same day.
74	Hildebrant.	P. Busch Inaugural Dissert., Berlin, 1889.	...	Size of an orange. Contents: Intestine. Irreducible.	Radical operation.	Cure.	Age at operation, 8 hours. Remnant of diverticulum of Meckel, a cord coming out to be inserted in the sac.
75	Porak.	Presse Medicale, Dec. 30, 1899.	...	Size of a plum. Contents: Intestine and part of lower border of liver.	Radical operation.	Cure.	Operation one hour after birth. Slight protrusion on coughing or crying remained.

NO.	SURGEON.	REFERENCE.	SEX.	DESCRIPTION.	TREATMENT.	COURSE.	REMARKS.
76	Monti.	Arch. für Kindhkd., 1899, Bd. xxvii, 412.	...	Circumference, 34 cm. Contents: Liver, spleen, pancreas, stomach, small intestine, large intestine, except descending colon.	Moist dressing.	Death.	Died from peritonitis on the fourth day. Coils of intestine bound by vascularized membranous deposit. Liver very adherent.
77	Monti.	Idem.	Male.	Small, containing intestinal coils.	Antiseptic dressing.	Death.	Died eighth day in collapse. Presented abdomino-pelvic fissure, exstrophy of bladder, anal atresia, and spina bifida.
78	Czyzewicz.	Wiener med. Wochenschr., Feb., 1899.	...	Half size of an orange. Opening very large. Contained intestine.	Protective dressing.	Death after 3 weeks.	After separation of cord, wound commenced to granulate.
79	Czyzewicz.	Idem.	...	Large tumor, inclosing intestine.	Protective dressing.	Death.	Died after some hours. Symptoms of peritonitis.
80	Bylicki.	Idem.	Male.	Size of an apple. Contained intestine. Opening large.	Protective dressing.	Cure.	Seen again after 10 years. At level of umbilicus a radiating cicatrix of size of 4 kreutzer piece. No separation.
81	Baracz.	Idem.	Male.	Opening 10 cm. by 8 cm. Contents: Liver, stomach, and small intestine.	Radical operation.	Death.	Age at operation, a few hours. Hernial sac excised. Intestines reduced under unclean linen. Reduction difficult. Sutures very tight. Died after some hours.
82	Schramm.	Idem.	Female	Size of a goose's egg. Opening, 3 cm. Contained small intestine.	Antiseptic dressing.	Cure.	Seen again 7 years later. At level of umbilicus, radiating scar. No separation.
83	Schramm.	Idem.	Female	Size of an apple. Op'g., scarcely 4 mm. Contents: Small intestine, cecum, and ascending colon.	Radical operation.	Death.	At first wound progressed normally. Wound almost healed. Erysipelas, sixth day. Death on eighth day.
84	Coley.	Medical Record, November 4, 1899.	...	Size of large orange. Organs adherent in sac. Irreducible.	Extraperitoneal operation, with drainage.	Cure.	Operation under chloroform 22 hours after birth; lasted 30 minutes. Two months later, slight protrusion.
85	Coley.	Medical Record, November 4, 1899.	...	Large as a child's head. Contents: Liquid, liver, part of large and part of small intestine.	Radical operation.	Healed.	Incision of sac allowed about 250 gm. of straw-colored fluid to flow out. Reduction impossible on account of extensive eventration. Three weeks later child was still living.
86	Hallet.	Revue de Gynecol. June, 1900.	Female	Size of fist. Opening narrow. Contents: Small intestine, with diverticulum of Meckel, adherent, and cecum, with its appendix. Irreducible.	Radical operation.	Cure.	Child's age, 2 hours. Chloroform. Resection of appendix and of diverticulum. Seen again 5 months later, showed radiating scar without separation.

V.—CASES NOT IN ANY OF THE PREVIOUS TABLES, BUT COLLECTED BY THE AUTHOR OF THE ACCOMPANYING REPORT.

87	Hackney.	Medical and Surgical Reporter, Philadelphia, 1887, vol. 56.	...	Hernial tumor, size of adult fist. Opening 2 inches in diameter. Transparent coverings, through which could be seen large and small intestines.	No attempt at reduction nor operation.	Died in 3 days.	Bowels moved. Child took nourishment. Died of general peritonitis.
88	K. Hedman.	Finska Läkarsällsk. Handlingar, December, 1897; Gaz. Hebdomadaire de Med. et de Chirurg., Mar. 20, 1898, Tome iii, No. 23, N. S.	...	Contained liver and small intestine, which could be seen through the transparent wall.	Reduction. Resection of sac. Suture of abdominal walls.	Cure.	Child weighed 3,600 gm. Anesthetic, chloroform. Presented no other abnormality. Adhesions of liver to sac wall. Body cavity relatively small.
89	von Habs.	Med. Gesellschaft zu Magdeburg; Münch. med. Woch., 1898, Bd. 45, No. 11, p. 346.	...	Entire liver in the hernial sac. Irreducible.	Radical operation. Excision of sac. Liver reduced. Urachus closed by a suture. Suture of abdominal wall by layers.	Death in 4 days.	Died from exhaustion. Wound conditions found normal. No other abnormality except patency of urachus, discovered during operation to have persisted.
90	Described in the accompanying report.	Male.	Circumference, 30 cm. Grayish above, and purplish and more transparent below. Cord at left and slightly above middle. Contents: Part of liver, part of small and large intestine. Hernial opening between 4.5 cm. and 5.5 cm.	Radical operation attempted but unsuccessful owing to impossibility of controlling eventration. Sutures.	Death after 4 days.	Operation under chloroform at age of 30 hours. Healthy, and presented otherwise no abnormality. Adhesion of liver to sac wall. Body cavity relatively small.

giving little encouragement in a majority of cases and accepting death as inevitable.

Lindfors confines his use of the term "radical operation," to that of abdominal section together with freshening of the cutaneous edges and suturing, although the completed operation of Breus involves an opening of the abdomen. Strictly speaking the operation by Pochhammer, 1846 (No. 19), became a radical operation by reason of his opening the sac to relieve adhesions of the liver, although he applied only simple ligature to close the hernial opening.

Lindfors' second table, accompanying his article in 1893, brought together 31 cases of congenital umbilical hernia, *reported whether cured or not*, all before 1891. He had repeatedly written on the subject and in 1889 his table contained 13 cases up to that date since 1882. In 1890 Macdonald, of Albany, N. Y., published a table, including his own case, which embraced 19 operative cases, and 12 treated expectantly. Berger, reporting 2 cases operated upon by himself, added those which had been reported previous to 1893. Schramm added a number of cases in a paper with a table published in Vienna in 1899; and, finally, Hallet, from Paris, published in June of the present year a table in which he includes such cases as he has gathered from the literature since 1893, and this last is the most satisfactory statement of the subject yet made.

In adding the case I have reported herewith, I wish also to submit those other cases which have come to my notice in the literature of the subject. The table as prepared by the writer comprises 90 cases, the treatment of which, with results, may be summarized as follows:

Radical operation: Laparotomy, freshening wound-edges and suturing.....	44
Healed.....	42 (= 95.6%)
Died.....	21
Result unknown.....	1
Simple ligature.....	1
Healed.....	1
Percutaneous ligature.....	3
Healed.....	1
Died.....	2
(Including Breus' first case, and Bryant's second case, Nos. 33 and 34 in Table 1, cases healed 3, = 60%)	
Extraperitoneal operation of Olshausen.....	5
Healed.....	5 (= 100%)
Total operative cases.....	73
Healed.....	49 (= 67%)
Died.....	23
Result unknown.....	1
Expectant treatment.....	15
Healed.....	7 (= 47%)
Died.....	8
Treatment, unknown or impossible.....	2
Died.....	2
Total (1882-1900).....	90

In this summary perhaps the most striking fact is the percentage of cases healed after operation by Olshausen's method, and of this it is proper to enter a word of explanation, as well as some detailing of the method, before proceeding to discuss the ordinary radical operation. Olshausen's report appeared in 1887, and he described his procedure as having the particular advantage of avoiding the opening of the peritoneal cavity. He made first an oval incision through the skin near the edge of the defect at the base of the tumor and carried it down only to the peritoneum. The edge of skin toward the defect, together with the outer membranous covering of the hernia, was separated from the under-

lying sac of peritoneum. Even the interposed mucous tissue, or Wharton's jelly, is removed, until the peritoneum is as free as possible from all adherent tissue. It is then gathered into folds by a few stitches to obliterate the cavity and the whole is dropped into the abdominal wound and the edges and, if possible, the deeper tissues drawn together over the opening and sutured with silk. In Benedict's case (No. 39) this last closing was effected by silver pins and figure-of-eight sutures, but with no particular advantage.

This operation is admitted to be applicable to those cases where a large hernial opening makes the eventration less easy to control, and critics have generally limited its special recommendation to these cases. At best the treatment by Olshausen's method has proved itself a means for lessening the probability of death from peritonitis, besides making a smaller cicatrix than would result from expectant treatment. In these cases it saves the life of the patient, but can scarcely be said to have cured the hernia. In nearly every one reported, the course of the case was that of failure of union, suppuration, and finally a cicatrix which after healing and contraction were complete, admitted of limited protrusion of the bowel. It may be granted that even this is a gain in that class of cases to which it has been said the operation should be confined.

Lindfors recommended the following technic: After complete anesthesia under chloroform the hernia is reduced if possible; the sac is then opened; adhesions separated and reduction completed. The sac is then excised and the skin-edges vivified, the umbilical vessels tied and separate rows of deep and superficial sutures passed. His most particular provision, that in regard to antiseptics, becomes to us, in the form of asepsis, a matter of course. He dissects around large adhesions, such as are frequently found to bind down the liver, in order to avoid excessive hemorrhage, allowing the excess of tissue to be reduced with the organ. Where necessary the hernial orifice may be enlarged along the linea alba to make reduction possible. The diverticulum of Meckel or the vermiform appendix may be removed in the manner ordinarily adopted.

In Hallet's conclusions on the subject, he says: "Intervention should be as early as possible after birth; waiting endangers the membranes from gangrene and peritonitis; and radical operation is always the most rational if we have the means and assistance at hand." In his analysis of the cases where the time after birth before operation is given in the reports, he supports the above statement by the following summary:

In 58 cases operated upon within 36 hours after birth, 15 deaths.....	= 26%
In 7 cases, within 48 hours, 3 deaths.....	= 43%
In 2 cases on third day, 1 death.....	= 50%
In 4 cases after third day, 4 deaths.....	= 100%

This scale of percentages surely bears testimony to the value of prompt and radical action.

Finally, it is to be observed that a rational treatment of congenital umbilical hernia is based upon two ideas the acceptance of which is comparatively recent and whose absence gave the condition its former hopeless prospect. These two things are aseptic practice in surgery and a better understanding of embryological development.

Journal on Sea-Sickness.—A unique publication has recently been started in Paris, entitled *Le Journal de Mal-de-Mer*. It is devoted entirely to the subject of sea-sickness.

The Philadelphia Medical Journal

A Weekly Journal Owned and Published by The Philadelphia Medical Publishing Company and Conducted Exclusively in the Interests of the Medical Profession

JAMES HENDRIE LLOYD, A.M., M.D., *Editor-in-Chief*

JULIUS L. SALINGER, M.D., *Associate Editor*

Assistant Editors

JOSEPH SAILER, M.D.

F. J. KATTEYER, M.D.

Surgical Interference in Gastric Ulcer.—Some idea of the steady advance of surgery into fields formerly considered essentially medical can be had by reading the excellent results recently reported as obtained from the surgical treatment of gastric ulcer by a number of different surgeons. We recently reported in the JOURNAL an interesting case by Dr. Wharton and Dr. Musser. Dr. Mayo Robson in a clinical lecture reported in the *British Medical Journal*, February 2, and abstracted in this JOURNAL, February 23, shows the wonderful decrease that has been brought about in the mortality of this condition by surgical intervention, not only in cases of perforation and of gastrorrhagia, which threaten to be fatal, but in the chronic cases as well. Robson's own mortality in operations for gastric ulcer is below 5%, which includes those done for hemorrhage and perforation. When one considers that the mortality rate of gastric ulcer medically treated is variously stated as from 20% to 50%, the great saving of life by surgical interference is very apparent. Of course no one would suppose that the mortality of all operations done for gastric ulcer and its complications would be found to be as low as that of Mr. Robson, who has had a very extensive experience in this particular branch of surgical work; but, there is no reason to suppose that with greater experience and improvement in technic, the surgical treatment of this condition may not become more universally employed and yield in the hands of others the good results shown by Robson. When one considers the immediate and remote dangers of ulcer of the stomach; namely, perforation with general peritonitis or subphrenic abscess; hemorrhage, which may prove fatal; stenosis of the pylorus; hour-glass contraction, and dilatation, then it would seem that if surgery offers a safeguard against these dangers, it should be called to the patient's aid. A patient with a chronic gastric ulcer which has refused to respond to treatment, is hardly as safe as one with an irreducible hernia. Undoubtedly medical treatment should take first rank in the treatment of ulcer of the stomach, and should be carefully carried out for a reasonable time, but, in cases which prove obstinate, which bleed repeatedly, or which recur after apparent healing, then surgery, it has been shown, can accomplish a great deal. The particular surgical operation that has to be done upon the stomach will depend upon the condition and situation of the ulcer. Where the ulcer is large and situated

at the pylorus, Robson has found gastroenterostomy to be more successful than pyloroplasty or pylorotomy, although in certain cases these operations are to be preferred. A great improvement in the method of performing gastroenterostomy is the attachment of the bowel to the posterior instead of to the anterior wall of the stomach. The latter is easier of accomplishment, but it does not give the physiological rest to the stomach that the posterior operation affords, and where a button is used to make the anastomosis there is much less likelihood of its finding its way into the stomach instead of into the bowel. The question now to be decided, since surgical interference has won its place in the treatment of gastric ulcer, is the time at which it is best to resort to surgical operation. Its absolute necessity in cases of perforation and of pyloric stenosis is unquestioned, and as regards the other cases, we can probably not do better than follow the advice of Mr. Robson, who thinks that cases of gastric ulcer which do not yield to careful medical treatment, which show a tendency to bleed, and which recur, should be operated upon. The safety of the operation of gastroenterostomy in the hands of experienced surgeons is shown by the fact that in his last 20 cases, Robson has not had a single bad or fatal result.

The Antiseptic Treatment of Enteric Fever.

It is now generally admitted that enteric fever is a self-limited disease, running its course in uncomplicated cases in from 21 to 28 days. The specific bacterium, the bacillus of Eberth, is conceded to be the exciting cause. It is not our purpose to inquire minutely into the pathology and the course of the specific bacteria after they have once found their way into a susceptible organism. After a period of incubation varying between two and three weeks (average 18 days) the characteristic phenomena of the disease are produced. It is quite necessary to bear this in mind when reflecting upon a treatment which has for its purpose the rendering of the intestinal tract antiseptic. Supposing this were possible (it is well known that under normal circumstances the bowel cannot be cleared of bacteria, which under many conditions may take on virulence), what effect would such a treatment have upon the specific bacteria which were present during the period of incubation and which had already produced their toxins, which after their absorption had

given rise to many of the symptoms of the disease, such as the dilated pupil, the dry throat, the diarrhea, the fever, etc.? How can a so-called antiseptic treatment, at least three weeks after the effects have been produced, control such manifestations?

The bacillus of Eberth is found in the evacuations some time between the tenth and sixteenth day of the disease. It is found in the spleen, the liver, the bone marrow, the blood, etc. While so-called intestinal antiseptics may serve a useful purpose in the control of some of the abdominal symptoms which may become unduly prominent, such as the diarrhea, tympanites, etc., they cannot under any circumstances favorably influence or *abort a self-limited disease*, in which a long period of incubation has allowed the bacteria and their toxins to produce these harmful effects.

Our only hope of a scientific treatment, which will contain all the essentials of an antiseptic and abortive treatment, rests upon an antitoxin serum.

Problems in Fermentation by Yeast.—According to the *Revue Scientifique*, the subject of the fermentation of sugar by the action of the yeast-plant has recently been investigated, with some interesting results. The subject has interest for physicians, because, as will be seen, it tends to throw light on some allied problems in bacteriology. The fermentation of sugar, as is usually taught, is caused by a low vegetable organism, known as the yeast-plant. This plant takes in the sugar and gives off carbonic acid and alcohol. In 1897, Büchner, a German investigator, announced that fermentation was not dependent on the actual presence of the growing yeast-plant, but that the process was maintained just as well by a liquid extract, which he had made from the yeast-plant itself. This extract is called a zymose. More recently some English experimenters have gone over this ground, in order to determine whether the fermentation caused by this zymose is identical with that caused by the yeast-plant itself; and especially whether the usual products—alcohol and carbonic acid—are obtained in the same proportions, and whether the amount of sugar transformed is in exact proportion with the quantities of these substances produced. They have found that the proportion between the alcohol and carbonic acid varies greatly, and that the exact proportion between the amount of sugar that disappears and the quantities of carbonic acid and alcohol that are produced is not maintained. In other words, a large quantity of sugar disappears and is not accounted for. This would seem to show that the yeast-extract, artificially produced, is not so potent as the yeast-plant itself, and that its potency is only maintained for a while. This whole process, as can be readily perceived, is analogous to what occurs in the case of many pathogenic bacteria. These minute organisms probably act by producing toxins, which are analogous to the yeast-extract, and these toxins become

gradually reduced in strength. By taking advantage of these facts pathologists are able to obtain a preventive serum.

Impositions on Medical Witnesses.—Since the recent remarkable utterance of one of the judges of the Philadelphia bench, which was referred to in these columns on February 9, many physicians have expressed their opinions to us about their treatment by lawyers when called as witnesses in court. Some of these opinions have been favorable to the legal profession, while others have been decidedly the reverse. Some physicians claim that medical witnesses are greatly imposed upon by the lawyers, particularly in cases of civil suits for damages. The gist of these complaints is about as follows: The physician receives a subpoena, which sets forth that, laying aside all his routine duties, he is to appear before the court at a certain hour of a certain day as witness in a certain case. This case is placed on the court calendar for that day in company with several others. The physician leaves his work, and goes to the court-room at the appointed hour and stays there until noon, when a recess is declared for an hour or two and he, as a witness, is excused for that length of time. At two o'clock the court reassembles and the physician is obliged to remain in the court-room for two or three hours more listening to the wearisome details of cases that do not concern him. This may be repeated for several days, until the case is so far behind that it cannot be reached at that term of court, and the witness is excused until the next term. A physician is very likely to think that he has just cause for complaint when required to waste almost an entire day listening to the arguments of learned counsel in cases that do not interest him. We are personally aware of an accident case that has been in the hands of a lawyer since 1895, in which the medical witness has been summoned twice a year for three years, and which is not yet settled. Some lawyers (not all) seem to have no consideration for physicians, especially for the younger ones, in this matter. If the lawyer in charge of the case would always arrange with his medical witness (as is often really done) for the accommodation of both, that when the case is actually called for trial the witness should be telephoned for, the latter could get to court and give his testimony in ample time. It always takes time, usually more than one-half hour, to call a jury, to administer the oath, to state the case to the court, and to examine the plaintiff, and in that time of preliminaries the physician can reach the court-room from almost any part of the city. In addition to the element of waste of time there is the question of compensation. The witness fee is entirely inadequate to compensate a physician for a day's work. Of course, in the case of a man engaged as an expert witness the fees are fixed by private agreement, but even in these cases there is no reason why an expert should be asked to waste his time in court.

While some of these complaints are just, there is, it must be freely conceded, another side to this question. Some members of the bar are exceedingly courteous and careful in endeavoring to put expert witnesses to as little inconvenience as possible. Of this we have frequently had agreeable personal experience. Lawyers claim that they themselves are even more frequently than physicians, the victims of the law's delays. They too have to waste valuable time in court. The truth is that there are many kinds of lawyers, just as there are many kinds of doctors, and all are not equally considerate of other men's rights. In this era of the telephone we think there is less excuse than formerly for robbing a doctor of his time, and we are sure that among the better class of lawyers there is no disposition to do so.

Physicians and Temperance.—The National Woman's Christian Temperance Union is out in a circular to physicians, and especially to the editors of medical journals, appealing for aid in its crusade against the use of alcoholic drinks. The authors of this circular claim that their most effective allies are those physicians who do not prescribe alcoholic liquors, but allow alcohol a very limited sphere of usefulness, or none at all, in the practice of medicine. They state in effect that they are endeavoring to do missionary work in the cause of total abstinence by using the teachings of such physicians, and they evidently want to make it appear that the medical profession as such must become a sort of auxiliary of the W. C. T. U. if the evils of liquor drinking are ever to be fully abated. There is indeed in the tone of the circular a little suggestion of a disposition to prescribe to the medical profession what it shall prescribe (or not prescribe) in the way of alcoholic stimulants.

We think the day is probably far distant when the medical profession as a body will be willing to subscribe to all the dicta that underlie the crusade against drink. As a profession it allows to its individual members a wide latitude, both of opinion and of practice, in the matter of the use of alcohol. As a profession, moreover, if it has a prejudice on any one subject, it is against the enforcing of the extreme views of individuals upon people in general, and against taking its cue from outside sources as to what it shall prescribe in the treatment of disease. The whole question of alcohol—its use, its abuse, its control, its place in medicine—is too vast for discussion within the limits of a circular or an editorial; but we are willing to say that the medical profession is certainly more fully alive to this question, and better acquainted with some of its details, than any other body of men in the world, and yet as a profession it would not endorse many of the things that are both said and done by the advocates of prohibition. Science has not yet demonstrated that alcohol is an unmixed evil, and that it has no place in the treatment of disease. Any attempt to misrepresent

the medical profession on this subject, or to try to make it appear that it has formed any unnatural alliances with outside crusading organizations, is at least somewhat premature.

Influenza as a Cause of Appendicitis.—That the poison, or germ, of influenza sometimes expends its force upon the intestine, is a well-known fact. Intestinal catarrh, with or without bloody discharges, has been observed in epidemics of grip, and has been claimed by good observers to be one of the effects of the disease. From this conception of an intestinal catarrh it is but a step to the conception of an appendicitis due to the same cause—the grip. This idea has been held and advanced by some clinicians, and is in accord with the idea that appendicitis is in fact always an infectious disease rather than the result of a trauma by a foreign body. We have always regarded this idea as still a theoretical one, and are not aware of any statistics that go to prove that appendicitis is more prevalent during or just after an epidemic of grip than at other times. A cablegram now announces as a piece of news that M. Lucas Championniere has just demonstrated to the French Academy of Medicine that one of the chief causes of appendicitis is the grip. For a piece of news, coming all the way from Paris, this sounds rather stale in the ears of American physicians.

As in the case of every medical announcement that sifts through the newspapers, this report from Paris is tangled up with a lot of sensational and incredible nonsense. One statement is to the effect that a well-known Philadelphia surgeon had said that at least one-third of Philadelphia's population have had appendicitis due to grip and to the eating of meat. As this would give about 400,000 cases of appendicitis in this city, the size of this canard can easily be estimated. It is clearly in the domain and within the capacity of the city editor to criticise such science, and to edit such cablegrams before they reach the press.

Endophlebitis.—In a recent interesting paper, read before the Pathological Society of Philadelphia, Dr. Arthur V. Meigs has described a new instance of this somewhat rare affection. He says that diseases of the veins have been by no means exhaustively studied. The word itself, while not new, cannot be said to be in common use. It is adopted in this connection in distinction from the ordinary phlebitis, so often used in medicine to describe the disease commonly called "milk-leg" and other similar inflammations of the veins. The endophlebitis of Meigs corresponds almost exactly to the affection known as endarteritis, and the term serves to call attention to the similarity of the disease in the two kinds of bloodvessels. In Dr. Meigs' case, that of a male adult, the veins in some places appeared as nearly solid cords instead of being thin-walled tubes, as is natural. There was much thicken-

ing of the intima, but the muscular coat was the more affected, while in the adventitia there was no evidence of disease. The intima was composed of fibrous tissue and presented the appearance commonly seen in diseased arteries. On the other hand the muscular coat, which occupied two-thirds of the entire thickness of the vessel wall, was unlike anything usually described in diseased bloodvessels. This thickening of the muscular coat was evidently caused by an overgrowth of fibrous tissue; hence it was not an hypertrophy, and instead of reinforcing the muscular coat had the effect of destroying it.

These changes are described minutely by the author in his paper, and should be studied in the original to be fully appreciated. The patient in whom they occurred was an Italian stone-mason, 25 years of age, who had had syphilitic infection $1\frac{1}{2}$ years previously; otherwise he was in good health and had been a man of fairly good habits. He was admitted to the hospital with an attack of vomiting and diarrhea, with pain in the epigastrium and with precordial distress. The heart's action was slow and exceedingly irregular, but there was no evidence of hypertrophy or valvular disease. There was some stiffening of the radial arteries, but the most noteworthy changes were in the veins. A small vein, for instance, extending across the dorsum of the foot was felt and seen to be distinctly thickened. Its unnatural thickness and hardness could easily be distinguished by passing the finger back and forth across it. It felt like a minute cord, instead of almost disappearing when compressed as a healthy vein does. This vein was excised and was the object of microscopic study, to which reference has been made. The patient presented no evidence of kidney disease, but he had not entirely recovered from his cardiac symptoms at the end of two months when he left the hospital.

In describing the nature of these changes, Dr. Meigs supposes that most observers would attribute this change to syphilis, and he also thinks that this etiology is probable. Syphilis undoubtedly produces vascular disease, as is well known, but its effects have mostly been described in the arteries; and changes in the veins, such as those described, are certainly not commonly reported. This observer thinks, however, that it would be a mistake to believe that syphilis is the only cause of such changes. He has been a careful and systematic student of diseases of the vascular system and has observed similar changes in the veins of persons suffering with other disease. He calls attention to the fact that diseases of the veins have by no means been so thoroughly studied as diseases of the arteries, and that it is probable that the veins are much more subject to disease than is commonly supposed. The case upon which he bases his observations was unique from the fact that the specimen was taken from the living subject.

Leukocytosis.—The doctrine of phagocytosis, heralded by Metschnikoff, the principle of chemiotaxis, advanced by Pfeffer, and the researches of Buchner, Deny, Martin Hahn, Goldscheider and Jacob, Löwy and Richter, and others upon the bactericidal and antitoxic secretions of the leukocytes, are all of interest when dealing with the problem of leukocytosis. Virchow suggested the term "leukocytosis" as meaning a transient increase in the number of white corpuscles in the blood. In our opinion Cabot's comprehensive definition is well worthy of general acceptance at the present time, "an increase in the number of leukocytes in the peripheral blood over the number normal in the individual case, this increase never involving a diminution in the polymorphonuclear varieties, but generally a marked absolute and relative gain over the number previously present." Although within the last decade much valuable statistical material has been collected, yet we are far from possessing anything like a comprehensive knowledge of leukocytosis in varied pathological states. As a striking example we might refer to constant leukopenia present in enteric fever and the value of repeated blood-counts through the course of this disease which will indicate the subnormal range in a given case. Thus the onset of beginning peritonitis from perforation might be overlooked from the blood-count alone if but a single observation showed an apparently normal or slightly increased count, whereas if such a count was one of a series the contrast would be suggestive of an inflammatory complication. Thus, again, in cases of malignant disease which should give rise to a leukocytosis we frequently have a modifying factor which complicates the clinical blood picture. We refer to starvation, which may occasion a hypoleukocytosis in esophageal cancer with obstruction. With such a complication the blood-count is modified by the two diverse factors. In our present state of knowledge we have no measures at our command to differentiate by the blood-count alone inflammatory or infectious from malignant diseases. The condition of temporary concentration due to the sudden loss of fluid from the body through excessive sweating, profuse diarrhea or other allied conditions often gives rise to an increase in the number of colorless corpuscles which may be a source of error. We shall not attempt to point out the various errors arising from faulty technic which are patent to the experienced hematologist, but it may be mentioned that the researches of Chantemesse and Ray have showed us that in their observations the number of leukocytes, when the blood is taken from the cold finger is less by 50% than in a count made from the warm finger.

It will require extended study and the compilation of accurate statistics to unravel the many-sided question of physiological leukocytosis. The many circumstances giving rise to the increase in the white corpuscles

show the constant association of this change with systemic disturbances and its consequent importance. The simplicity of the method of determination should stimulate us to more constant and careful observation. The value of leukocytosis as a clinical index is comparable in a measure to that afforded by the range of temperature. The classical observations of Wunderlich established for us the value of the clinical thermometer and threw much light upon that which was hidden and obscure. Is it too much to hope that the thorough study of leukocytosis may afford us a guide of equal value?

Death of Professor Pettenkofer.—The news of the death of the illustrious bacteriologist and hygienist, Professor v. Pettenkofer, will be received by the scientific world with deepest regrets. The *Frankfurter Zeitung* states that Dr. Pettenkofer, who was a diabetic, had infected himself with a knife with which he opened an abscess on his neck. Like his deceased brother he was constantly fearing mental derangement, and during a spell of melancholia shot himself during the night in his apartments at the royal residence. A man of profound learning, indefatigable energy and strength of character, he gained the admiration of all with whom he came in contact. He was instrumental in elevating the subject of hygiene, and he endeared himself to the inhabitants of Munich by his scientific devotion to all matters pertaining to the public health. At the age of 83, beloved, respected and preeminent, Pettenkofer passed away, leaving an indelible impression for future generations.

Pistol Shots.—Hough gives the results of experiments made by him to show the marks produced by pistol shots at various distances. He used white blotting-paper, which he considered took about the same amount of powder-mark as the human skin. He found that it is not possible to determine with absolute accuracy from the mark alone what is the caliber of the weapon used or the distance from which it is fired. If the mark is a smut without tattoo, the shot was fired at a distance not over 6 inches; if the mark consists of a tattoo with distinct smut at the center, then the distance was not over 2 feet; if the mark consists of a bullet-hole alone, the range was not less than 4 to 6 feet, if a 22-caliber was used; 7 to 9 if a 32, and 9 to 12 if a 38 or 41.

Scarlet Fever.—Prof. Gibert (*Revue Medico-Pharmaceutique*, Jan. 15, 1901) divides scarlet fever into normal cases, not necessarily free from danger, and abnormal or complicated cases. The former are usually seen, with angina, fever, eruption, desquamation of the tongue, followed by desquamation of the body, taking in all about 6 weeks. The abnormal cases may be abortive, as is so common in France, severe, or hemorrhagic, though this is rare. Among the complications are severe angina, albuminuria, edema, etc. The eruption settles the diagnosis. The prognosis should always be guarded. Isolation in bed, sponging, should the fever persist, and milk diet constitute the main treatment. All cases should be reported. And, finally, disinfection must be carefully done. [M.O.]

Reviews.

A Manual of Medicine. Edited by W. H. ALLCHIN, M.D. Lond., F.R.C.P.F.R.S. Ed. Volume II. New York and London: The Macmillan Company. Price, \$2.00 a volume, in cloth.

The second and concluding volume of this manual of medicine sustains the excellence of the first. The subjects have been treated ably and as briefly as is consistent with thoroughness. The editor has moulded the work with painstaking care, and we have failed to note the frequently observed discrepancies in books of similar character in which the various contributors at times conflict. The fact that the work is in two volumes may militate somewhat against its general adoption by students, but this inconvenience is more than compensated by its satisfactory character. This volume, from the pens of thirteen contributors, deals with diseases caused by parasites, those produced by poisons introduced into the body, the poisons produced by perversion of general nutrition as uremia, diseases of the blood, diabetes, gout, chronic rheumatism, osteomalacia, rickets, leontiasis ossea, otitis deformans, akromegaly and rickets. This in general serves as an outline of the contents. [T.I.C.]

Die Therapie beim engen Becken. Die Indikationsstellung zu operativen Eingriffen unter Zugrundelegung der in den Jahren 1891-99 an der Universitäts-Frauenklinik in Leipzig (Geheimrath Prof. Dr. Zweifel) beobachteten Geburten beim engen Becken. Von Dr. B. KRONIG, Privatdocent in Leipzig. Leipzig: Published by Arthur Georgi. 1901.

The author in this little brochure of 213 pages has given a comprehensive description of the treatment of contracted pelvis which is largely based upon statistics taken from Dr. Zweifel's Women's Clinic in the University at Leipzig. The text is enriched by numerous tables of labors in primipara and multipara, and the subject is so grouped as to be rendered easily accessible for purposes of reference. The author illustrates the different portions of the work with descriptive cases, and from the point of view of the management of this obstetric complication, he considers the various operations of prophylactic version, craniotomy, the induction of premature labor, symphysiotomy and Cesarean section. A large list of authors and their contributions to the subject, the conclusions of which he has employed in his work, adds considerably to the value of the book, which should find a place in the library of all obstetricians. [W.A.N.D.]

Diseases of the Heart; Their Diagnosis and Treatment. BY ALBERT ABRAMS, A.M., M.D., Consulting Physician for Diseases of the Chest, Mt. Zion Hospital and the French Hospital, San Francisco. Illustrated. Pp. 172. Chicago: G. P. Engelhard & Co. Price, \$1.00 net.

Condensation of so important and extensive a subject as "diseases of the heart" is a task so difficult that we feel some hesitancy in expressing criticism of the work of Abrams, which would be obvious in a more elaborate treatise. In the description of chronic adhesive pericarditis we fail to find mention of Broadbent's sign. On page 54 the author states the following: "Mitral Stenosis—Pulse small, irregular, with increased frequency." On page 119, in dealing with the description of mitral stenosis, he informs us that "the pulse is smaller in volume than normal, but regular." In the discussion of mitral stenosis he makes the following statement (on page 118): "The brunt of the burden is borne by the right auricle and ventricle which become hypertrophied." Again, on page 36, we find the following: "In mitral obstruction it is the left auricle which primarily hypertrophies to overcome the narrowed mitral orifice. Later the right ventricle hypertrophies." Such contradictory statements cannot fail to impair the value of the work. The illustrations appear crude and typographical errors are also found. We feel that the brevity of the work and the errors would greatly mar its usefulness as a work for students. [F.J.K.]

International Clinics. Edited by HENRY W. CATTELL, A.M., M.D. Philadelphia, U. S. A. Volume IV. Tenth Series 1901. Philadelphia: Published by Messrs. J. B. Lippincott & Co. Price, \$2.00 a volume in cloth.

This volume of *International Clinics* contains several noteworthy contributions and, as a whole, is of unusual excellence. We might mention especially Professor B. Grassi's contribution upon "Mosquitoes and the Prophylaxis of Malaria," "Massage in Ranaud's Disease," by Douglas Graham, and the "Role of the Blastomycetes or Ferments in the Etiology of Cancer," by Roncali. John B. Deaver reports several interesting operations including the Kraske operation for carcinoma of the rectum and neurectasy of the sciatic nerve.

One-third of this volume is devoted to a monograph (by the editor) which deals with the etiology and morbid anatomy of various diseases. The letter T is reached in this portion of the entire monograph. It is designed to aid students "who are about to pass examination in medicine and pathology and as a work of ready reference for those interested in these subjects."

We cannot accept the value of such a work in the *International Clinics*, even if it were done to our entire satisfaction, but in the present instance the average quiz compend would supply the student with far better material than is found in this monograph. There is scarcely a classification which is satisfactory, and many are woefully behind our present knowledge upon their respective subjects. We may criticise at random. Under pernicious anemia, for instance, in the description of blood-changes it is stated that there is an increase of "neutrophilic whites." The term so used is a poor one. Polynuclear or polymorphonuclear neutrophils are far preferable. Leukocytes are diminished in number. There is a relative increase or absolute increase in the lymphocytes and a small percentage of myelocytes are present in pernicious anemia. No mention is made of the presence of megaloblasts which are of great diagnostic value. In discussing the blood in the anemias no mention is made of the gross appearance of the blood which is important. Lloyd Jones' theory is not mentioned under the etiology of chlorosis. The etiology of malaria is disposed of with a statement that it is "a true hematozoon." In the definition of diabetes the continuous presence of sugar is not regarded as noteworthy of mention. It seems unfortunate to mar the value of the *International Clinics* with such a monograph. We grant that the editor had a task of unusual difficulty confronting him, but we believe it to have been an entirely gratuitous one. [T.L.C.]

Prophylactic Measures against the Pest.—In the report by Prof. v. Ermengem (*Revue Medico Pharmaceutique*, Jan. 15, 1901) upon the pest epidemic in Glasgow, August, 1900, he says: The pest probably entered upon a ship from a foreign port, which showed no suspicious signs upon reaching quarantine. It is not known whether persons or merchandise brought in the infection. The epidemic was not widespread, perhaps because the rats were not affected. Nor were the cases, on the whole, severe. The diagnosis was not difficult in severe, or bubonic cases. Bacteriologic examination was indispensable in pest pneumonia and in mild cases. Anti-pest serum furnished encouraging, but not positive results. Where isolation, disinfection, etc., are well carried out, such an epidemic is soon limited. [M.O.]

Contribution to the Clinical Study of Osseous and Osteoarticular Tuberculosis in Old People.—Moret (*Gaz. Heb. de Méd. et de Chirurg.*, Feb. 3, 1901, 48me Année, No. 10; Paris Thesis, 1900 1901, No. 31) out of 3,925 patients has found 178 cases of osseous and osteoarticular tuberculosis. The course of the disease appears to be chronic and its evolution slow. The prognosis is, however, rendered more grave by the always menacing possibility of a propagation to another organ. The gravity of the disease is still further dependent upon the localization of the affection. The seat of the disease, according to the order of frequency, is as follows: Foot, ribs, knee, sternum, wrist, hand, vertebral column. While conservative treatment is the rule in children, in old people, on the other hand, economic operations should be advised. [J.M.S.]

Correspondence.

THE INFLUENCE OF HEREDITY.

By JOHN K. MITCHELL, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE error in the example under the above editorial heading in your last number is a small one—but somewhat vitiates the result. A gelding you say has never won the Derby. This might argue for the superiority of "entire" horses and mares were it not that the reason why a gelding has never won the race is that a gelding has never tried to. The conditions of the race limit it to "colts and fillies."

Another statement there made is of more moment. "Mares have won races far less frequently than stallions." Having regard to the comparative numbers of the two sexes in training, I doubt if this is true. But if it refers only to the Derby a glance at the list of entries for any year will suggest a good reason. Counting up the first year's record which I chance upon I find that of 22 starters for the Derby that season, but 2 were mares.

For general purposes of hard and steady work every horseman will tell you a mare will outwork and outlast a stallion or a gelding, whether the work is for a day or a year.

SALINE INFUSIONS IN THE TREATMENT OF PNEUMONIA.

By CLARENCE A. PENROSE, M.D.,
of Baltimore, Md.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In your February 16 number an article by Dr. James K. Crook appeared entitled "Recent Progress in the Treatment of Acute Lobar Pneumonia." I was much surprised at the little emphasis the doctor gives to saline infusions in the treatment of this disease, and felt that if a wrong impression were given to the medical profession it should be corrected.

Salt infusion is almost a routine treatment in desperate cases at the Johns Hopkins Hospital and has been employed in a number of cases of pneumonia, with most favorable results, by our best local physicians in their private practice. As I had the honor of inaugurating this treatment of pneumonia while on the staff of Dr. Osler, and published the first work on this matter (*Johns Hopkins Hospital Bulletin*, July, 1899), about one year after my first case, it is surprising that Dr. Crook seems unaware of that article and of recent favorable comments on this method in other journals.

All articles published since mine seem to omit what I consider to be a very striking point in the effect of salt-infusion in pneumonia, i.e., its marked action as a respiratory stimulant, proved by Dr. Hunt's work on dogs in Dr. Howell's laboratory, and its favoring the absorption of oxygen, probably for this reason.

Since my first case, infused February 14, 1898, and published later with two others, I have had the opportunity of seeing saline infusions further tested and have probably employed this method more in private work than anyone. This additional experience only confirms me more and more in my opinion, that such infusions are most valuable in the treatment of pneumonias of severe grade, when employed by one conversant with the method, and who understands the significance of the second pulmonic heart-sound. As stated in my article, bleeding is often a most necessary adjunct to infusion and sometimes it is imperative. I take the

liberty of sending you a reprint of my article, which I scarcely think Dr. Crook should overlook.

QUEEN VICTORIA AND THE USE OF CHLOROFORM IN OBSTETRICAL PRACTICE.

By J. C. REEVE, M.D.,
of Dayton, O.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN all the notices of the late Queen Victoria, her noble life, and her influence for good, I have failed to find a single word in regard to the importance of her example in accepting chloroform during labor, until the article in your issue of February 9. In that article, due appreciation of her influence in promoting the use of anesthetics in obstetrical practice is expressed. May I be permitted to call attention to the fact that this has already been done, and several years ago, in our medical literature. In Vol. I, of Hirst's *American System of Obstetrics*, 1888, article "On the Use of Anesthetics in Labor," I have tried to give due expression to the importance of the Queen's action in this matter, and appreciations of its great influence in promoting the use of anesthetics in labor. The date was 1853, but a very few years after chloroform was first used for surgical anesthesia, and when the *Lancet*, then the leading medical journal of the world, commenting on the administration, said: "In no case could it be justifiable to administer chloroform in a perfectly ordinary labor." In that article I close by saying: "The illustrious sovereign, whose reign has seen so many notable achievements, may congratulate herself upon a personal participation in the greatest one of the age, or of any age, so far as the suffering of her sex is concerned. In all time to come homage is due her for this service as the woman, rather than as the Queen."

A QUESTION OF ORIGINALITY.

By D. T. SMITH, M.D.,
of Louisville, Ky.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I SEND you today a copy of the *American Practitioner and News*, of July 10, 1886, containing an article by myself, reprinted from the *Southern Pharmacist* of February, 1884. The article was read to the Orleans Parish Medical Society in October, 1883, and shortly afterward submitted to Dr. Rudolph Matas, then the editor of the *New Orleans Medical Journal*, for publication, and he told me he would give it the leading place in his next issue. In the meantime the *Journal* passed into the hands of a coterie of physicians, and when Dr. Matas submitted my paper they unanimously voted it too visionary and fanciful for a scientific journal and rejected it. In the succeeding February it was published in the *Southern Pharmacist*, a small pharmaceutical publication conducted by Ferdinand Larcas, Ph.D. It is useless to say how long these views had been held in a more or less crude form, but I may say that at that time I had never heard of Metschnikoff nor his doctrine, which as far as I know at the date of the rejection of my article had not been published in America. His observations, I believe, began in 1892. The article contains a number of errors too glaring now to need pointing out, but as a speculation so largely borne out by observations that have added another name to the immortals, I may be excused the selfish desire to have it appear in the columns of the PHILADELPHIA MEDICAL JOURNAL.

The article as read and first published was entitled, "The Role of the Leukocyte, or the Philosophy of Fever," and is here given.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

New Editor.—Francis R. Packard, of Philadelphia, has been made editor of the *American Journal of Medical Science*, vice Dr. Alfred Stengel, resigned.

The Maternity Hospital.—The twenty-seventh annual report of the Maternity Hospital, Tenth and Fitzwater streets, which has just been published, states that there were 90 applicants during the year, of whom 51 free and 5 pay-patients were treated.

Anatomy Prizes.—At the annual competitive examination just held at the Philadelphia School of Anatomy, Eighteenth and Buttonwood streets, by Professor W. Wallace Fritz, M.D., D.D.S., the first prize was awarded to Dr. Arthur Fritz, of Australia, for the best paper on anatomy and surgery. The second prize was awarded to Dr. Agnes W. Howes, of New York, for the best practical anatomical work. A large number of students received honorable mention.

Pennsylvania Hospital.—A committee consisting of John B. Garrett and John Story Jenks, of the board of managers, Dr. John B. Chapin, superintendent of the Pennsylvania Hospital for the Insane, and Dr. Thomas G. Morton, president of the medical staff, was appointed to make arrangements for the commemoration, early in June, of the one hundred and fiftieth anniversary of the founding of the Pennsylvania Hospital. Dr. Francis Olcott Allen, Jr., who graduated last year from the University of Pennsylvania, was appointed a resident physician of the hospital.

Vital Statistics of Philadelphia for the week ended February 23, 1901:

Total mortality	517
	CASES. DEATHS.
Inflammation of appendix 1, bladder 2, brain 21, bronchi 12, heart 1, kidneys 26, larynx 1, lungs 74, peritoneum 8, pleura 2, stomach and bowels 19	167
Inanition 20, marasmus 10, debility 4	34
Tuberculosis of lungs	64
Apoplexy 16, paralysis 6	22
Heart—disease of 41, fatty degeneration of 4, Uremia 12, diabetes 2, Bright's disease 5	45
Carcinoma of breast 3, stomach 4, uterus 3	19
Convulsions	10
Diphtheria	18
Brain—abscess of 2, dropsy of 1, softening of 2	59
Typhoid fever	11
Old age	5
Alcoholism	54
Cyanosis	6
Scarlet fever	22
Influenza 12, asthma 3, anemia 1, aneurysm of aorta 1, burns and scalds 3, casualties 11, congestion of lungs 3, cirrhosis of the liver 9, tuberculosis of the bowels 1, membranous croup 3, diarrhea 1, drowned 2, dropsy 4, epilepsy 1, erysipelas 1, fistula 1, gallstones 1, gangrene 1, hemorrhage from nose 1, hernia 3, jaundice 1, obstruction of the bowels 2, poisoning 1, rheumatism 1, arterial sclerosis 1, surgical shock 1, septicemia 4, sore mouth 1, suffocation 1, syphilis 1, teething 1, brain tumor 3, ovarian 1, ulceration of stomach 1, whooping-cough 3	53
	86

Neurological Society.—The stated meeting, held February 25, was opened by Drs. WILLIAM H. TELLER and F. X. DEBECUM, who exhibited **A case of astereognosis**. This condition was the result of an injury by a blow on the head, which caused a depressed fracture and a large subdural hemorrhage in the parietal lobule posterior to the fissure of Rolando. Astereognosis of the right hand is complete, the patient, a colored man, 30 years of age, being unable to recognize by the sense of touch any object placed in that hand. There is also tactile hypesthesia over the whole of the right side, this condition being more marked as the extremities are reached. Ability to locate simultaneously two impressions is lost and there is also a diminution of the faculty of locating a single impression.

Drs. GEORGE L. WALTON and WALTER E. PAUL, of Boston, by

invitation, read an admirable paper entitled **Astereognosis, with illustrative cases.** The value of this condition in differentiating hysteria from organic disease was pointed out. Among the points of difference is the fact that in astereognosis the patient cannot touch a certain point on the affected hand with the well hand without groping when the eyes are closed. In hysteria this is not present. Astereognosis occurs in both cortical and central lesions and cannot alone differentiate between these locations. In none of the cases seen by these observers has pain or temperature sense been lost when the lesion was in the Rolandic areas. In one case the paralysis was limited to one foot. This furnished an opportunity to compare results with those obtained in the hands. Tests with normal subjects showed that the foot gave little reliability in distinguishing the size of objects which are round or square, but can distinguish long objects. In the case of astereognosis mentioned, designated points could be located apparently as well as by the hand. The results of locating lesions by this method brings up the question of the advisability of surgical interference in cerebral disease. An occasional success indicates that the patient should be given the benefit of the chance when the lesion is local and near the cortex. Experiments on animals will be of little value in advancing the knowledge of astereognosis as the faculties concerned are not well enough developed. Control experiments on human subjects are of great value. In cases of hemiplegia without astereognosis the chances are in favor of a capsular lesion. A safe working plan is that when astereognosis only is present the lesion is at a point in the central parietal lobule. DR. DERCUM thinks it is justifiable to speak of a sensory and a motor astereognosis. DR. BURR said that it was wrong to speak of the stereognostic sense. Faculty is a better term. He believes that there is a part of the posterior parietal lobule which stores up, so to speak, the memory of things felt as other parts do the memory of things seen. The term stereognosis is a more accurate expression than is astereognosis. The subject was further discussed by DRs. LLOYD, SPILLER, and WALTON. Following the meeting a reception was tendered Drs. Walton and Paul at the University Club.

College of Physicians—Section on Gynecology.—The meeting of February 21 was opened by DR. JOHN B. SHOBER, who read a paper on **Varicocele of the broad ligament.** The etiology, symptoms, diagnosis, and treatment were considered and a case reported. The treatment adopted was simple ligation of the veins of both broad ligaments. The condition of the patient after 16 months is fully as bad as before operation. Catgut ligatures were used, which is believed to be largely responsible for the failure to cure. Dr. Shober also exhibited a specimen removed from a patient having primary tuberculosis of the fallopian tubes. Operation revealed general adhesions, a monolocular cyst of the right ovary, double pyosalpinx, and a large fibroid of the uterus.

DR. WILMER KRUSEN reported a case of **Ovariectomy in the eightieth year.** Cysts of both ovaries were removed, the patient making a good recovery. An interesting point was the slow growth of the cysts, a tumor having first been observed 26 years before operation.

DR. H. D. BEYER reported **The occurrence of fibroid tumors in 4 sisters, their mother, and grandmother, a maternal aunt, and 2 third cousins.** DR. E. E. MONTGOMERY believes there is no hereditary tendency to fibroids of the uterus. DR. J. G. CLARK thinks that the cases reported were only a coincidence, as is the case with any growth of the genital tract. He now pays but little attention to the family history in cases of suspected malignant disease.

DR. JOHN B. DEEVER read a paper entitled **Three dangerous operations—Repair of a lacerated cervix, dilatation, and curettement.** The paper was directed mainly to general practitioners and dealt with the indications for these operations and their danger when not done under proper aseptic precautions. Lacerations of the cervix had better be let alone unless there are special indications for treatment. A family history of malignant disease is an indication for operation at once. Washing out the uterus and packing with gauze are to be done only in infected cases. Curettement should be used only in carefully selected cases. The moral effect of the operation is nothing, and the effect

of operations *per se* should be relegated to the realms of Christian science. The reliability of the examination of curetted material in cases of suspected malignant disease is doubtful. Dilatation of the cervix or curettement should never be done in a physician's office. They should only be done after careful disinfection of the patient, and the operator and assistants should wear rubber gloves. Operations should be confined to surgeons and not be a prerogative of general practitioners. DR. MONTGOMERY stated that he considered it a crime for physicians to dilate or curet a uterus in their office. He does not permit such a patient to be up in less than a week. Digital examination in suspected malignant disease is preferred to microscopic examination of scrapings. The hereditary tendency of cancer of the uterus is questioned. DR. BARTON COOKE HIRST has had a satisfactory experience with the examination of scrapings by expert pathologists. Few men are competent to give authoritative opinions on such tissues, but when such men are employed the results are satisfactory. Dr. Hirst has been observing the results of operations upon the cervix until he is convinced that primary operation for a lacerated cervix is not warranted. At the end of 2 weeks a certain success may be attained. In institutions this time should be selected, the woman thus convalescing from the puerperium and the operation at the same time. DR. J. G. CLARK finds microscopic examination of curetted material to be of great value. The diagnosis of such material, however, is almost a special line of pathology, as many men who are, generally speaking, first-class pathologists will make mistakes in these instances. Dilatation of the cervix is a very dangerous procedure in old cases of gonorrheal infection. Patients with gonorrheal history should be most carefully studied before the operation is resorted to. DR. DEEVER has obtained distinct history of heredity in some cases of cancer. He takes exceptions to the statements that douching of the uterus is advisable after ordinary operations upon the cervix. He believes that fluid can be thus conveyed to the fallopian tubes.

DR. JOHN H. GIVIN reported a case of **infectious fever resulting in premature labor, peritonitis, and death.** The etiology of the case is obscure. Symptoms were indefinite, and operation at no time seemed to be indicated.

DR. J. M. BALDY read a paper on **Results in treatment of cancer of the cervix and the unreliability of statistics of the same.** The reports of 40 to 80% of cures are misleading and contrary to facts. They are published before a sufficient time has elapsed, or refer only to selected cases operated upon, the great majority of cases seen being refused operation as hopeless. Statistics of Germans are especially unreliable. Most cases of cancer of the cervix die, whatever be done for them. The hope of the future is a more careful clinical study of the symptoms and earlier diagnosis. In medical schools and textbooks too much stress is put upon laboratory diagnosis. Clinical manifestations must be studied, especially by country practitioners, that they may send cases for operation earlier. DR. DEEVER stated that very radical surgery was advisable only in cases seen early. The same rule holds good in these cases as in cancer of the breast—when the surrounding glands are involved the case is hopeless. In cancer of the breast, when the glands under the clavicle are involved, the removal of the entire growth is impossible. DR. E. P. DAVIS believes that a microscopic examination should be made in cases of incomplete abortion and the so-called molar pregnancies. DR. J. G. CLARK considers the statistics of German writers as generally very reliable.

NEW JERSEY.

Appointed Railroad Surgeon.—Dr. Paul M. McCray, surgeon at the Cooper Hospital, has been appointed surgeon and physician to the Pennsylvania Railroad Company, to succeed Dr. Dowling Benjamin.

NEW YORK.

New Pavilion at Eye and Ear Infirmary.—The new Platt Pavilion, for the isolation and treatment of cases of contagious ophthalmia, has just been opened at the New York Eye and Ear Infirmary. The building was erected to the memory of the late James N. Platt, and presented to the institution.

Professional Secrecy.—A bill has been introduced into the New York legislature to include nurses within the scope of sections 884 and 886 of the code of civil procedure, placing them in the same position as physicians, regarding revealing information obtained from patients while serving in a confidential and professional capacity.

New York Skin and Cancer Hospital.—The Governors of the New York Skin and Cancer Hospital announce the following course of clinical lectures on Syphilis by members of the Visiting and Consulting Staffs, on Wednesday, at 4.15 P.M.:

March 6.—Syphilis as a Disease: Modes of Infection: Extra-Genital Syphilis, by L. Duncan Bulkley, M.D.

March 13.—Skin Manifestations of Syphilis, by L. Duncan Bulkley, M.D.

March 20.—Infantile Syphilis, by A. Jacobi, M.D.

March 27.—Syphilis of the Mouth, Nose, Throat, and Larynx, by D. Bryson Delavan, M.D.

April 3.—Syphilis of the Eye and Ear, by David Webster, M.D.

April 10.—Syphilis of the Nervous System, by Edward D. Fisher, M.D.

April 17.—Syphilis of Internal Organs, by Edward G. Janeway, M.D.

April 24.—Syphilis of the Bones, and Surgical Relations of Syphilis, by Willy Meyer, M.D.

May 1.—Synopsis, Conclusions, and Treatment of Syphilis, by L. Duncan Bulkley, M.D.

NEW ENGLAND.

New England Baptist Hospital.—The New England Baptist Hospital has bought a piece of land in Roxbury, where it already occupies 35,862 square feet.

Appointments.—F. W. Spalding, M.D., has been appointed visiting ophthalmologist to the Long Island Hospital, Boston Harbor. John J. Magrath, M.D., has been appointed attending surgeon to the Harlem, N. Y., Hospital.

Acute Infectious Diseases in Boston.—For the week ending at noon, February 20, 1901, there were reported to the Board of Health, of Boston, the following cases of acute infectious diseases: diphtheria 105, scarlatina 31, measles 48, typhoid fever 4.

Dr. Samuel Camp.—The death of Dr. Samuel Camp, the oldest physician and surgeon in Southern Berkshire, Mass., occurred February 24. He was 72 years of age, and a native of Winsted, Ct. He graduated in 1851 from the University of New York. He served during the Civil War as surgeon of the 27th Massachusetts regiment, and from 1877 to 1892 was Medical Examiner for Southern Berkshire. He was a member of the Massachusetts and Berkshire medical societies.

CHICAGO AND WESTERN STATES.

Oakland Medical College.—The new building of the Oakland Medical College will be ready for students by September 1, 1901.

Compulsory Inoculation.—The Council of Sioux City has passed an ordinance compelling the inoculation with antitoxin of all members of families in which there is a case of diphtheria.

Professor William Pleen Dead.—Dr. William Pleen, professor of physical diagnosis, at Hamline University, and one of the best known physicians of Minneapolis, died February 21, from pneumonia.

Value of Antitoxin.—It has been estimated by the Health Department of Chicago that 4,500 lives have been saved in that city during the last 5 years by the use of antitoxin in the treatment of diphtheria.

Mendota Insane Asylum.—The state board of control elected Dr. E. L. Bullard of Waukesha, to succeed Dr. W. B. Lyman, of Eau Claire, as superintendent of the Mendota Insane Asylum, which position Dr. Lyman resigned some time ago.

Omaha Medical Society.—The following officers were elected: Dr. Bryon B. Davis, president; Drs. Gertrude Cusaden and Rufus D. Mason, vice-presidents; Dr. Joseph M. Aikin, secretary; Dr. Millard Langfeld, treasurer, and Drs. Harry M. McClanahan, Benjamin F. Crummer and Andrew B. Somers, board of censors.

Smallpox in Wisconsin.—The village of Salem is the seat of a smallpox sensation and it is stated that over 700 people employed in the harvest have been exposed to smallpox. The village is used by ice companies for cutting ice on the lakes and a few days ago a laborer was taken ill with what was supposed to be influenza. It is claimed, however, that the man had a well developed case of smallpox before leaving the village. Cases are further reported at Tomahawk, Manitowoc and Neenah.

Bacteria in Library Books.—Dr. F. A. Kuflewski, chairman of the special committee appointed by the public library board of Chicago to consider the advisability of sterilizing the books in the library for the purpose of preventing the spread of disease, recommends that some system be adopted for freeing the pages of the volumes from bacteria. He said that all of the 50 books examined by him during the investigation were found to be more or less infected. He said there was no doubt that disease was spread by the books, and advised that a system of sterilizing the volumes by the dry process be adopted immediately.

Dr. Smith Dead.—Dr. Mayo G. Smith, the companion and friend of Mark Twain and inspiration of the novelist's "Doctor," "Innocents Abroad," is dead at Colorado Springs. Dr. Smith was born in Newburyport, Mass., August 19, 1816. He was one of the first graduates of Oberlin College, and was an intimate friend of Horace Greeley, starting life as a preacher and later as the reporter employed by Greeley on the *Tribune*. He went to California in 1849, joined the regular army; later became rich and traveled with Mark Twain. He was master and part owner of the first ship that sailed from San Francisco to Australia. Dr. Smith was the author of two works on ether and chloroform from experiments he conducted. For several years he gave his attention to medicine, and later was associated with Morse, in completing the telegraph and constructing the first line between Washington and Baltimore.

Meeting of the Chicago Pathological Society, February 11, 1901, Dr. L. Hektoen, President.

DR. THOMAS R. CROWDER described three cases of osseous stylohyoid arch. The stylohyoid arch is a constant structure in the higher vertebrates. In many, as the horse, cow and sheep, it is completely bony; in man it is largely ligamentous. Developmental defects with more or less ossification are not infrequently found, but complete bony arch is rare. The three cases presented were not recognized before death. The anomaly is to be looked upon as a developmental defect and not as an ossification of the stylohyoid ligament once developed in the normal way. It has no clinical significance beyond the possibility of fracture—an unlikely accident.

D. F. G. HARRIS reported a case of blastomycetic dermatitis in a woman 78 years old. The growth was located on the gluteal region and commenced four years ago as a pimple, which became a roughened area of intense itching and later became apparently denuded. The growth was 11 centimeters long by about 6 centimeters wide, having an elevated border bearing flattened papillomatous outgrowths which overhung the floor, the latter being covered with villous-like epithelial projections interspersed with areas of ulceration. The entire growth was movable on the underlying tissues; there were no secondary growths on any part of the body, nor were there any evidence of syphilitic infection. Microscopic examination showed a hyperplasia of the rete mucosum which grew down into the corium in branching, coral-like projections. In these epithelial downgrowths were miliary abscesses containing the blastomycetic organisms which were present in groups of 3 or more. Many of them were in the process of budding. There were no cultures made from this case on account of the diagnosis not having been made clinically. In the discussion of Dr. Harris' paper, DR. LIEBERTHAL referred to a case recently observed, in which a provisional diagnosis of syphilis was made, where the blastomyces were found in

sections. He still held to his original diagnosis. H. T. RICKETS said that the histology of blastomycetic dermatitis is a specific one and entirely different from that of tuberculosis and syphilis. H. G. ANTHONY spoke of the points of difference between blastomycetic dermatitis and the syphilitic and tubercular lesions resembling it. L. LOEB called attention to the fact that blastomycetic dermatitis has not been produced experimentally. W. E. COATES compared blastomycetic dermatitis to certain diseases in plants. He considers the organisms observed in the skin lesions as spores of fungi.

F. G. HARRIS stated that his case was treated with iodids for 3 weeks without any improvement.

DR. LE COUNT demonstrated diffuse secondary carcinoma confined to the lymph-channels of both lungs of a man who died from carcinoma of the stomach while in the service of Dr. Kramps at the St. Elizabeth Hospital; the condition was correctly diagnosed during life. At the necropsy the usual large metastatic tumor nodules were found in the liver together with an extensive involvement of the peripancreatic, retroperitoneal, peribronchial and peritracheal lymph-glands; the adrenals were the seat of a very extensive carcinomatous growth; there were small tumors in the outer parts of both kidneys. The primary tumor from which all these metastatic growths arose was located near the pylorus and showed no features other than are often observed in gastric carcinomata. The lungs were alike in appearance; both possessed very extensive subpleural, linear, branching and tortuous carcinomatous growths in the lymph-channels as well as tumor masses in the lymph-channels of the deeper parts of the lungs. There were no nodular growths in the lungs as are observed in consequence of the embolism of tumor-cells. The lungs were fresh, no microscopic examination having been made, but the gross appearance supported in all its details the opinion that a retrograde lymphatic metastasis had occurred in these channels from the lymph-glands at the roots of the lungs.

MARTIN H. FISHER reported the results obtained from a study of the toxic effects of formaldehyde and its aqueous solution, formalin. The inhalation of formaldehyde is accompanied by marked inflammatory changes throughout the respiratory system. Dyspnea, depression of temperature, tachycardia, weak pulse, and vomiting follow the introduction of formalin into the stomach. Sudden death may result. The severity of the symptoms and the degree of histologic disturbance bear no relation to the strength or quantity of the injected formalin. The gastritis is characterized by intense congestion, necrosis, and leukocytic infiltration. Intraperitoneal injections produce a fibrinohemorrhagic peritonitis of varying intensity according to the strength of the solution. The peritonitis following chronic formalin poisoning, produced by injecting small amounts of dilute formalin intraperitoneally, is accompanied by great connective-tissue proliferation and a striking eosinophilia. Subcutaneous formalin injections produce marked exudation and leukocytic infiltration. The introduction of formalin into the conjunctival sac is followed by an iritis, which, when a single drop of the concentrated chemical is used, may be sufficient to permanently injure the eye. In whatever way formalin is introduced into the body, certain systemic changes result. Degenerative changes and focal necroses are found in the liver and kidneys. The leukocytic infiltration following the introduction of formalin is characterized by the eosinophiles appearing first; these are followed by the other polymorphs; last of all appear the mononuclears. It is believed that differences in osmotic pressure are to be held accountable for the exudation. The death of the cell is accounted for in two ways: (1) By disturbances in osmotic pressure, and (2) by a deleterious chemical action—probably the reducing power of formaldehyde.

SOUTHERN STATES.

Dr. John B. Haden has recently been elected lecturer on ophthalmology, otology, rhinology, and laryngology, in the medical department of the University of Texas.

Baltimore County Medical Association.—The February meeting of the Baltimore County Medical Association was held, February 21, at the Baltimore Medical College. The officers are: Dr. H. Burton Stevenson, president; Dr. R. C. Massenburg, corresponding secretary; Dr. H. S.

Jarrett, treasurer. Addresses were made by Drs. L. M. Allen, L. Gibbons Smart, H. B. Stevenson, and B. F. Bussy.

Annual Meeting of the Association of Medical Officers of the Army and Navy of the Confederacy.—The annual meeting of this association will be held in Memphis, Tenn., in connection with the annual reunion of the United Confederate Veterans, May 28-30, 1901. Any further information desired will be cheerfully furnished by Drs. Malone or Elcan, of Memphis, or Dr. Deering J. Roberts, secretary of the association, of Nashville, Tenn. It is stated that considerable preparation is under way in Memphis for this meeting.

Richmond (Va.) Notes.—The next annual meeting of the Tri-State Medical Association, embracing Virginia, North and South Carolina, will be held in Richmond, February 26, 27, and 28.

The State Board of Health at its recent meeting elected Dr. R. W. Martin, of Lynchburg, president, and Dr. P. A. Irving, of Richmond, secretary.

For the past week there were reported to the city health office 3 cases of diphtheria, 1 of scarlet fever and 5 of smallpox. Influenza is decidedly on the decrease.

CANADA.

(From Our Special Correspondent.)

The extent of leprosy in Canada is shown in the last annual report of the Minister of Agriculture. In this appears a sub-report from the medical superintendent of the Lazaretto at Tracadie, N. B., Dr. A. C. Smith, for the 12 months ending the 31st of October, 1900. There are today 20 inmates at the Lazaretto, 13 males and 7 females. Their ages range from 19 to 64 years; and 7 of the inmates may be classified as being in the first stage, 12 in the second, and 1 in the final stage of the malady. There were 4 deaths during the past year; and 8 new cases were admitted from the surrounding districts in New Brunswick. During the year Dr. Smith, having received favorable reports from foreign leper institutions on the use of chaulmoogra oil and creolin, made several trials on the less advanced cases with encouraging results. This, however, is not the only place where leprosy exists in Canada. On Darcy Island, off the coast of British Columbia, there are confined 5 lepers—all Chinese males. One is maintained by the province of British Columbia, and 1 each by the municipalities of Victoria, Vancouver, Nanaimo and Kamloops.

The latest news from the Yukon shows that the citizens of Dawson have been experiencing some pretty severe weather and much sickness. On January 9 the thermometer stood at 50.5 below zero, and on January 15 at 68.5 below. For 9 days the average minimum temperature was 60 below. This intense cold in the Yukon valley was accompanied by the regular dense white mist peculiar to that country. During the cold spell an epidemic of rabies broke out among the dogs of the town, and most of them had to be impounded to preserve the citizens from being bitten. Typhoid and pneumonia have been very prevalent for the past two months; and a complication of the two, "typho-pneumonia," has also been prevalent and has proved very fatal. It is said that the pneumonia appears first, developing in the usual way; then at the time the crisis should occur, abdominal troubles with other marked symptoms of typhoid set in, resulting in fatal collapse. Consequently, during those two months the death-rate has been very high, and several well-known and popular citizens have succumbed to the fatal complication.

Christian Scientists, both in the province of Ontario and British Columbia, have come in recently for very severe condemnation at the hands of two coroners' juries. At Peterboro, Ont., a death occurred recently from typhoid fever under treatment by these people; and in returning their verdict on the investigation into the cause of death in this case, the coroner's jury expressed their opinion that for the safety of society, further legislation is necessary, and stated that it was time the provincial parliament gave this matter their serious consideration. They further expressed their strongest detestation and condemnation of the practice. The other case was that of a child of tender years, a resident

of Victoria, B. C., whose death was due to asphyxiation from laryngeal diphtheria. In this verdict the jury deliberately stated that the "Christian Scientists" who treated, or rather maltreated, the little boy, "did unlawfully kill and slay the said child." These two verdicts are indeed healthy indications that the public in Canada are awakening to the dangers of permitting these dangerous people prosecuting their practices upon deluded and helpless victims. The intelligence of these two juries is to be commended in thus endeavoring to preserve the health of the community from utter disregard of isolation in communicable diseases.

War on the white plague may now be expected to be pushed in a vigorous and systematic manner in the Dominion of Canada. In response to a call of the Governor-General, Lord Minto, a large number of prominent citizens and a great many of the most eminent medical men in Canada met in conference in the city of Ottawa on the 14th and 15th of February and formed and perfected organization for the prosecution of this most important work. Several resolutions of importance were submitted for discussion during the progress of the convention, in the main calling upon the central government and the governments of the respective provinces to render aid to municipalities or groups of municipalities to provide for the erection and maintenance of suitable sanatoria for consumptives. Amongst others taking part in this conference were Sir William Hingston, Dr. T. G. Reddick, M.P., and Professor Adams, of Montreal; Sir James Grant, Ottawa; Dr. Fred. Montizambert, Director-General of Public Health at Ottawa; Dr. P. H. Bryce, Toronto, and Dr. H. H. Chown, president of the Canadian Medical Association, Winnipeg. A constitution was adopted and the name of the Association decided on was the Canadian Association for the Prevention of Tuberculosis. Branches will be formed immediately in those provinces where similar associations do not already exist. Honorary life patrons will pay \$1,000; honorary life members, \$50, and yearly members, \$1.00. The Earl of Minto was elected honorary president, and Sir James Grant, president.

The National Sanitarium Association is handing around its third annual report. Five years ago Mr. W. J. Gage, of Toronto, contributed \$25,000 for this work. A little later on Mr. Hart A. Massey, since deceased, contributed another \$25,000; the association was at once formed, a splendid site of 50 acres at Gravenhurst, in the Muskoka region, selected; a charter obtained from the Dominion Parliament in 1896, and the result was that a spacious administration building and three cottages were opened in the summer of 1897. A free department for the poor will soon be completed. During the three years since the Sanitarium opened it has received 371 patients, of whom 47 are still in the establishment. It has discharged as apparently cured 57 cases, and with disease arrested 95 cases, while 78 others have been discharged with marked improvement. The report of the Medical Superintendent, Dr. E. C. Ashton, for the year ending October 1, shows that 48 were in residence at the end of 1899; admitted during the year, 141; total treated during the year, 189; 47 remained in the institution at the end of the year, thus leaving 142 to be reported on. Of these one patient was twice admitted, leaving 141. Of these 24 were discharged apparently cured; 40 with disease arrested; 32 with marked improvement; 27 unimproved; 16 failed and 2 died. The sites of the pulmonary lesions shows that the apex of the right lung only was affected in 47; the base in 1; general, 18; left lung apex, 4; base, 1; general, 13; both lungs—both apices, 46; both bases, 3; right apex and left base, 6; left apex and right base, 5; and general infection, 3. Of laryngeal tuberculosis, 1 was apparently cured, 3 much improved, 2 stationary, and 2 failed. Patients remaining one month or under, 18; 14 of these gained in weight, 2 lost and 2 neither gained nor lost. Patients remaining from two to three months, 51; gained in weight, 31; lost, 8; and neither gained nor lost, 12. Patients remaining over three months, 72; gained in weight, 59; lost, 6; and neither gained nor lost, 7. It is considered that with a longer stay in the institution even better results can be obtained.

Hospital Burned.—News has been received from Victoria, B. C., that the hospital attached to Tokio University was burned on January 29 and that 21 patients were burned to death, 10 patients and 11 nurses injured.

MISCELLANY.

Miners' Hospital.—Arrangements have been made to erect a handsome hospital at Sclocan, B. C., at a cost of \$5,000. Dr. Farin, of Nelson, has been appointed superintendent.

Condemns the Indelible Pencil.—A Chicago physician has protested against the use of the indelible pencil, which he charges has been the cause of innumerable sore lips and fingers. The doctor says the coloring matter in the indelible pencil is of the same nature as that which caused the death of Senator Cushman K. Davis, of Minnesota, in whose case the dye was in the stockings.

Obituary.—DR. HENRY F. BATCHELDER, at Danvers, Mass.—DR. I. N. BOWSER, at Millersville, Pa., on February 24.—DR. PIERCE B. FAGIN, at Santa Cruz, Cal., on February 23, aged 82 years.—DR. S. A. MERCER GIVEN, at Clifton, Pa., on February 23, aged 41 years.—DR. WILLIAM BOOZE, at Carthage, Ill., on February 20, aged 73 years.—DR. GEORGE L. KIRBY, at Raleigh, N. C., on February 19.—DR. B. F. LONG-STREET, at Cincinnati, O., on February 21, aged 51 years.—DR. J. H. RENNER, at Lagro, Ind., on February 21, aged 70 years.—DR. DANIEL HANDEL, at Onawa, Ia., on February 19.—DR. C. E. GISSY, at Breese, Ill., on February 21.—DR. ABBOTT HODGMAN, of New York City, on February 26, aged 69 years.—DR. CHARLES P. AMET, at Waukegan, Ill., on February 25, aged 88 years.—DR. L. T. BRITTINGHAM, at Hannibal, Mo., on February 24, aged 80 years.—DR. E. T. TIDWELL, at Camden, Ark., on February 25.—DR. THOMAS O'REILLY, at St. Louis, Mo., on February 24, aged 74 years.

Health Reports.—The following cases of smallpox, cholera, yellow fever and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended February 23, 1901:

Disposal of Booth's Body.—At the monthly dinner of the Medical-Legal Society, Dr. George L. Porter, of Bridgeport, read a paper entitled "Reminiscences of the Assassination of President Lincoln," and, according to the *Washington Post*, said the following in the course of his address:

"I was in medical charge in Washington after the murder of Lincoln, and had unequalled opportunities for observation.

The descriptions of the disposition of Booth's body are most inaccurate.

"The body was taken to Washington, identified by many persons, and afterward taken in a rowboat to the Washington Arsenal, and in the dead of night, in the presence of the military storekeeper, four enlisted men, and myself, the only commissioned, was hidden in a place so secret that never, to this day, has it been correctly described. We were requested by Secretary Stanton to keep silent, and no man during these 35 years has yet told. I believe the body was finally given to the family under agreement never to mark by mound or monument where it should be placed."

Changes in the Medical Corps of the U. S. Army, for the week ended February 23, 1901:

KENDALL, Major WILLIAM P., surgeon, is relieved from further duty in the division of the Philippines, and will proceed to Fort Slocum, to relieve Captain Charles M. Gandy, assistant surgeon.

GANDY, Captain CHARLES M., assistant surgeon, will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

BELL, JOSEPH L., acting assistant surgeon, will proceed to Fort Cook for duty.

GREENLEAF, Colonel CHARLES R., assistant surgeon-general, is relieved from duty in the division of the Philippines, to take effect June 1, and will then proceed to San Francisco, Cal., and report to the commanding general, department of California, for duty as chief surgeon of that department.

JACKSON, FREDERICK C., acting assistant surgeon, now at San Francisco, Cal., will report to the commanding general, department of California, for assignment to temporary duty in that department.

GILHULEY, JOHN J., acting assistant surgeon, will proceed from Bridgeport, Conn., to Governors Island, N. Y., and report in person to the commanding general, department of the East, for assignment to temporary duty.

REED, Major WALTER, surgeon, is detailed as a member of the board of Medical officers appointed February 2, to meet at the Army Medical Museum building, for the examination of candidates for admission to the medical corps of the Army.

MOSELEY, Major EDWARD B., surgeon, now at San Francisco, Cal., is relieved from further duty in the division of the Philippines, and upon the expiration of the leave of absence granted him December 8, will proceed to Fort Sheridan for duty, to relieve Major George W. Adair, surgeon.

ADAIR, Major GEORGE W., surgeon, will proceed to Manila, P. I., where he will report for assignment to duty.

PENROSE, Major GEORGE H., surgeon, will upon the expiration of such leave of absence as may have been granted him by the commanding general, department of California, report to that officer for assignment to duty.

WILLIAMS, ALLIE W., acting assistant surgeon, is assigned to duty at Fort Columbus.

HORNE, WILLIS S., acting assistant surgeon, is assigned to duty at Fort Sam Houston.

CABLE, GEORGE L., acting assistant surgeon, is granted leave of absence for 20 days.

WILLIAMS, ADRIAN D., acting assistant surgeon, upon relief by First Lieutenant Weston P. Chamberlain, assistant surgeon, will proceed to Fort Greble, for temporary duty.

CHAMBERLAIN, First Lieutenant WESTON P., upon expiration of his leave of absence, will proceed to Fort Adams for duty.

BACHE, Colonel DALAS, assistant surgeon, is granted leave of absence for 3 months from about March 1, on surgeon's certificate.

The following-named dental surgeons will proceed from Washington, D. C., to Philadelphia, Pa., on business pertaining to the medical department: JOHN S. MARSHALL, ROBERT T. OLIVER, and ROBERT W. MORGAN.

COX, SHELBY G., hospital steward, Army General Hospital, Presidio, will be sent to Fort Crook for duty.

McKEE, JOHN, hospital steward, San Juan, P. R., is transferred to the Army General Hospital, Washington Barracks, for duty.

BAILEY, GUY G., acting assistant surgeon, leave of absence granted January 31 is further extended 10 days.

BAMBERGER, RAYMOND S., hospital steward, (appointed February 18, from private, hospital corps), San Juan, P. R., is assigned to duty at his present station.

Changes in the Medical Corps of the U. S. Navy, for the week ended February 23, 1901:

HOLCOMBE, R. C., assistant surgeon, detached from the "Glacier," and ordered to duty with detachment of marines at Pollok, P. I.

ROSS, J. W., surgeon, U. S. N., retired, by special order, department of Cuba, Feb. 15, 1901, to report to the chief sanitary officer, city of Havana, for duty.

Changes in the U. S. Marine-Hospital Service, for the week ended February 21, 1901:

GARDNER, C. H., passed assistant surgeon, granted leave of absence for 7 days.

KALLOCH, P. C., surgeon, granted leave of absence for 3 days from February 17.

SAWTELLE, H. W., surgeon, granted leave of absence for 30 days from February 20.

foreign News and Notes.

GREAT BRITAIN.

Appropriation to Combat the Plague.—The London county council has decided to spend £50,000 as a precautionary measure against the bubonic plague in London.

Presentation to Professor Schäfer.—A silver bowl and platters have been presented to Professor Schäfer, Jodrell professor of physiology at University College, by his colleagues and his pupils. They have also subscribed funds for the endowment of a Schäfer medal to be awarded for research in physiology.

CONTINENTAL EUROPE.

Obituary.—DR. JULIUS LAHMANN, hygienist, at Copenhagen.—DR. W. PASCHUTIN, at Petersburg.

Moscow.—Dr. P. A. Minakow was appointed extraordinary professor of jurisprudence at the University at Moscow.

Heidelberg.—Dr. Braus, demonstrator of comparative anatomy in Würzburg, has been appointed extraordinary professor at Heidelberg.

Medical Inspector.—Dr. Brendan MacCarthy has been appointed medical inspector under the Local Government Board for Ireland.

Professor Leopold Weiss, the well-known ophthalmologist and extraordinary professor at the University at Heidelberg, died at Mannheim, aged 52 years.

Suicide of Professor Pettenkofer.—A private telegram to the *Frankfurter Zeitung* states: "The renowned hygienist and President of the Academy of Sciences, Professor Pettenkofer, shot himself during the night at his lodgings in the Royal residence. Professor Pettenkofer was a diabetic. Recently he became infected by cutting an abscess from which he was suffering, with an unclean knife. He was 83 years of age." A later authentic dispatch states: "Professor Pettenkofer suffered from an abscess in the neck, and had been melancholic for some time. He feared psychical disturbances similar to his deceased brother; he obtained a revolver and shot himself in the temple during the night, while in bed."

Modern Pathology of Puerperal Sepsis.—A. Bass (*Centralblatt für die Grenzgebiete der Medizin und Chirurgie*, Vol. 3, No. 22, November 22, 1900) comes to the following conclusions: 1. The uterine cavity of healthy pregnant and parturient women that have not been meddled with is free from pathogenic organisms; this is likewise true in most cases of healthy women during the puerperium. 2. The question as to whether the vagina of the healthy pregnant, parturient and puerperant women that have neither been examined nor douched, is or is not free from pathogenic organisms cannot as yet be positively answered, notwithstanding that a series of observations seems to indicate the affirmative. 3. Autoinfection can only be considered when every probability of an external infection has been excluded; even then autoinfection contrary to Ahlfeld, is very rare. 4. The following bacteria have been shown to be the cause of puerperal sepsis: *Streptococcus pyogenes*, *Staphylococcus pyogenes aureus* and *albus*, *Bacillus coli communis*, *pneumococcus*, *typhus*, and *diphtheria bacilli*, and various obligate anaerobes, especially the *Bacillus aerogenes capsulatus* and the *Vibrio septique*. 5. The portal of infection is generally the endometrium (the placental area) where the bacteria not only directly enter, but may also gain access by means of their own surface growth. 6. The infection occurs either by the lymph- or blood-channels, rarely by both simultaneously. 7. A certain clinical differentiation in regard to the various forms of bacteria cannot yet be given; nevertheless the anaerobic infections are milder. 8. The blood-examination, with the exception of an eventual bacteremia and the findings of Kaminer (still requiring more substantiation), offers nothing characteristic for puerperal sepsis. 9. Antibodies are probably not formed in the blood in this condition; at least this has not been proved. [M.R.D.]

1.—Paul exhibits a patient, aged 43 years, suffering from an extensive inoperable cancer of the face. He had operated 8 years previously upon this patient for a rodent ulcer of the face which had resulted from an injury to the skin of the cheek when the patient was 19 years old. He thinks the present epithelioma started in the scar following the former operation. The appearances and histories of rodent ulcer and epithelioma, as well as their pathology, are carefully contrasted. [J.H.G.]

2.—Bunch reports the case of a girl, aged 3½ years, who presented a small, ringed patch on the right forearm, just above the wrist, and a second patch on the right shoulder. Microscopic examination of scrapings from these patches shows chains of large, squarish spores both inside and outside the hairs, and, in preparations treated with 6.8% liquor potassae solution, a segmented coarse mycelium which terminated in a fringe above the bulb, in the intrafollicular portion of the hair shaft, and outside the hair in the root sheath and in the connective tissue of the follicle. Cultures from minute portions of the affected hairs and from the scales grown on French proof agar showed a network of coarse aerial hyphae, radiating from the center, white in color, and terminating at the edge in tapering, somewhat pointed, processes. The child's father was a coachman and there was a horse in his stable that had been certified by a veterinary surgeon to have ringworm. There were two patches on the horse, one on the neck and one on the head, both of which were scaly, and covered with broken and twisted hairs, but which showed no sign of vesiculation. Microscopic examination of scrapings from these patches gave the same results that were obtained from the hairs of the child and cultures on the same medium proved to be almost identical with those obtained from the diseased areas of the child's skin. A second case of ringworm in man due to infection from animals was in the person of an hostler, aged 19 years, who presented a circular, scaly patch on the right side of the neck. Examination of scales from the lesion showed a network of abundant, fine, branching, irregularly septate mycelia, and mycelial threads could be made out running chiefly in the direction of the long axis of the hair. A diagnosis of microsporon was advanced until cultures had been made and then the opinion as to the character of the organism was confirmed. The hostler had been looking after a young horse with some pimples on his nose, and, on going to the mews, the author found that the animal had some indistinctly ringed vesicles above the right nostril, the hairs around which appeared to be irregular and broken. Cultures gave a rapidly-growing, white, downy mass, similar to that obtained from the lesion of the patient. In a third patient, a boy, aged 3 years, with kerion of the scalp, cultures showed alternate concentric rings of white and brown growth, with a delicate filiform border and a central raised prominence. Hairs from a terrier with which the child had often played proved to be infiltrated with typical microsporon, and cultures from these hairs resembled closely those obtained from the child's scalp. A fourth patient was a child, 4 weeks old,

who had a well-marked patch of tinea circinata on the left cheek. Cultures made from the patch gave a somewhat coarse growth of radiating, aerial hyphae, of a dull whitish color. A cat in the house, with which the child had played, had a patch on the neck from which the hairs had almost all come out. Cultures showed the same organism, with some cultural peculiarities that were probably due to difference in the medium employed. The fifth patient was a youth, aged 16 years, who had several well-marked patches of tinea circinata on the left arm and trunk. A large-spored trichophyton was found both within and without the hairs of the lesions, which, on cultivation, gave a somewhat coarse, white growth, very similar to that already described by other observers as being derived from the cat. From a patch on the patient's cat, which had been noticed to be mangy, a very similar culture was obtained. The sixth patient was a boy, aged 9 years, who presented 2 more or less circinate, smooth, almost bald patches on the scalp. Cultures gave an irregularly plicated growth, somewhat powdery, with a tendency to crack on the surface. Hairs from a cat in the house also contained an endothrix fungus. Cultures from these lesions on the cat proved to be very similar to those obtained from the boy. The seventh case was that of a girl, aged 13 years, with a patch of tinea circinata on the forearm. Cultures gave a dull, opaque, whitish growth, spreading somewhat irregularly from the center, and with a faviform appearance. The child had a pet canary, whose feathers had been coming out in patches and microscopic examination of these feathers showed an invasion by a fungus similar to that already demonstrated in the patient. Cultures from the bird, too, were faviform in appearance, and only differed in that the spreading edge was slightly more thickened. The eighth example was a case of ringworm of the beard in a man aged 29 years. Cultures gave a whitish, downy growth with a central prominence, and a fine striated edge, but in many of the original tube inoculations the growths were contaminated by staphylococci, and it was only with difficulty that a pure culture was obtained. The patient, who was a farm laborer, stated that one of the calves had ringworm. Hairs of these animals contained an endoethrix fungus, somewhat closely packed, so that the chain formation was not very evident. Cultures from these hairs gave a white aerial growth with a striated edge. The number of cases of ringworm in man having an animal origin must always be a very small percentage of the whole, and it must be remembered that one such case in a child is capable of serving as a source of infection to many more. Valuable though microscopic examination is for diagnosis, greater reliance must always be placed upon cultures. [J.M.S.]

3.—Morris and Dore have used electric light rays in the treatment of lupus vulgaris and rodent ulcer after the method of Finsen. They give some practical points concerning the technic. These points bear upon current, intensity of light, the focus, screens and pressure. The reaction varies in intensity according to the idiosyncrasy of the patient, but largely depends upon the intensity of the light at the time of exposure. Lupus vulgaris is the disease most benefited by this treatment and, although it has a marked effect upon rodent ulcer and other diseases, the bactericidal theory of its mode of action is not thereby disproved, although it negatives the supposition that it is specific for the tubercle bacillus alone. Apparently, however, there is some chemical or nutritional effect upon the tissues also to be taken into account. In all the cases treated by the authors the improvement has been marked and uniform, though in some cases very slow. In several cases of lupus vulgaris one application has been sufficient to cause the disappearance of a small isolated superficial nodule for the time. In an extensive case involving both sides of the face, a year with intervals of rest may be given as a rough indication of the duration of the treatment. The use of pyrogallie acid ointment, though not necessary for the success of the treatment, will, in cases where there is great thickening of the skin, considerably lessen its duration. In the case of an extensive rodent ulcer, in which the typical hard edge was in part absent, the effect of a single application was apparently to stimulate healing of the part to which the light was applied and was followed by rapid growth of healthy epithelium from the surrounding skin. In cases in which there was no ulceration, reddening and perhaps slight excoriation of the skin resulted from a

few applications and the growth gradually became softer, and finally disappeared without obvious breaking down of tissue. In small ulcers entirely surrounded by an indurated rolled edge, there was no visible effect at first, but after several continuous applications the discharge increased, and an inflammatory reaction occurred; at the same time the induration gradually became less marked, until a simple, punched-out ulcer with soft edge remained. On cessation of the treatment, healing took place with great rapidity as soon as the inflammation had subsided. In lupus erythematosus the effect has been marked, although not so certain as in lupus vulgaris. Although several cases have been treated in which the inner or outer canthi or lids were involved, there has not been any deleterious effect upon the eye itself. In one case in which the skin of the nose was treated, improvement took place in the mucous membrane, and the sensation of smell was said to have greatly improved. There are certain conditions that make a case unfavorable for treatment; these are scarring, pigmentation, great vascularity, great depth below the surface, the situation of the disease near the eye, on the eyelid, or on the mucous membranes, and great extent of the lesions. Notes of 6 cases are given. [J.M.S.]

4.—Sequeira has treated 12 cases of rodent ulcer by x-rays. The immediate result of the treatment is all that can be wished for, and the author feels justified in recommending the use of the x-rays, at least in those cases of rodent ulcer in which complete removal by the knife is impracticable. [J.M.S.]

6.—Whitehead recommends the use of the seton in the treatment of troublesome cases of migraine, and reports most satisfactory results from its employment. [J.H.G.]

7.—The effects of antityphoid inoculations in the 15th Hussars have been encouraging. The incidence of typhoid fever in the inoculated was represented by 0.55% and the mortality by 0.27%; while the incidence in the uninoculated was 6.14% and the death-rate 3.35%. [J.M.S.]

8.—Maclaren recommends the careful and thorough excision of superficial gummata, when they do not respond to a fair trial of mercury applied locally to the surface affected and by inunctions, or to increasing doses of potassium iodid. Very extensive dissection of fascia, sometimes extending down between the muscles, is necessary, but his results have been very satisfactory from this treatment. [J.H.G.]

10. Reflections on Therapeutics. HARRY CAMPBELL.

1.—Robson calls attention to the fact that gastric ulcer occurs in 5% of the community and that the mortality of this condition is from 10% to 50%. As soon as gastric ulcer is diagnosed the patient should be informed of the serious nature and the necessity of careful treatment, rest in bed, and long-continued care in diet. Robson's mortality from surgical treatment in this condition is about 5%. Probably 7% represents the mortality in all cases of gastrorrhagia.

Vicarious hematemesis at the menstrual period and post-operative hematemesis usually respond to medical treatment. But surgical intervention not infrequently is to be considered in these cases, though its results have not been satisfactory. It is difficult to account for postoperative hematemesis, injury of the omentum, general anesthesia, and sepsis have all been suggested as causes, and yet cases occur where none of these conditions exist. Robson thinks that the occurrence is dependent upon a reflex nervous influence. Recurrent venous hemorrhage, Robson thinks, will be most likely to be benefited by surgical treatment. The arterial bleeding is most responsible for the fatal cases, and may arise from small arterioles or from the larger vessels. It is impossible to tell the size of the vessel bleeding either from the amount of blood lost or from the length of the survival. The only help in such a case would be the diagnosis of the situation of the ulcer. Treatment should always be medical at first in cases of acute hematemesis, but if, after a few hours of medical treatment properly carried out, the bleeding is not arrested, or if, being arrested, it recurs, a surgical consultation should be had, with the idea of opening the stomach. In cases of recurring hemorrhage, Robson advises operation, even during the course of the bleeding. Technic: It is undesirable to wash out the stomach before operating on a bleeding ulcer. After the abdomen is opened, the stomach may be emptied by pressing the contents into the bowel. Frequently a puckering of the surface or thickening of the coats will indicate the site of the ulcer. Examination of the posterior wall is difficult, but if a slit be made in the omentum, two fingers can be pushed through it and the posterior wall invaginated. When no ulcer can be found in the stomach, the duodenum should be carefully examined. If an ulcer is present, it should be excised and its edges sutured. The cautery may be used, if excision is impracticable. Robson does not think that ligation of the main arteries of the stomach, as has been suggested, is advisable. When the pylorus is adherent, he thinks it advisable to do a gastroenterostomy, but if the pylorus be extensively ulcerated and free from adhesions, pylorotomy can be done. When the bleeding is general, and not from any vessel which can be ligated, gastroenterostomy by securing complete physiological rest would seem to offer the best chance for success. Robson strongly recommends the posterior operation, his last 20 gastroenterostomies done in this way having recovered without any untoward symptoms. Robson reports 5 cases operated upon for hematemesis. [J.H.G.]

2.—Dickinson delivered the second lecture on Considerations touching the pathology and relations of diabetes, on December 12, 1900. Reference is made to the liver as the organ which is concerned in the formation of glycogen. He gives the theory of Bernard stating that he believes the conversion of glycogen into sugar takes place in the liver, the latter substance then finding its way into the circulation. The opinion of Pavy is also mentioned, who believes that the liver produces glycogen in order to prevent the passage of sugar into the circulation. Both observers agree that in diabetes mellitus the blood is overloaded with sugar. Upon theoretical ground the author mentions that the excess is due either to improper removal or excessive introduction of sugar into the blood. As very large quantities are poured out with the urine (as much as 2 pounds per day) the idea of abundant introduction seems to be sustained. As a provisional theory Dickinson maintains that the morbid influence of the brain upon the liver (in the most common form of diabetes) is the important factor associated with this disease. The pathological change in the brain appears rather of an irritative nature than a paralytic condition. Some of the diseases of the pancreas must not be overlooked in the consideration of the etiology of this disease, but, as he has previously stated, the pancreas produces the less common form of diabetes. The author mentions that complete removal of the pancreas is followed by fatal glycosuria, while partial removal of the gland fails to produce this condition. After complete removal of the pancreas, followed by implantation of the portion of the gland into some part of the body, glycosuria does not develop. That diseased conditions of the brain are more frequently the cause of diabetes mellitus than pathological changes of the pancreas, should at the present time be upheld. In the treatment of diabetes the chief object is to control the existing symptoms.

The cause is beyond our reach. Much is accomplished by withholding sugar and starch from the food, especially in the mild cases; but it appears that in the more severe forms the nitrogenous principles of the blood are broken up into urea and sugar, therefore depriving the system of nourishment. He states that proper dieting, as a rule, is followed by good results, with very few exceptions. A full list of the articles included in the diet are not mentioned, reference only being made to the more important ones. Care must be taken not to institute the rigid restriction of the diet too suddenly. The patient should be encouraged to partake freely of water. Oncoming coma is sometimes prevented by the injection of aqueous solution into the veins. As to the medicinal treatment, he does not use opium, but recommends strychnia, sometimes in combination with tartrate of potash or phosphate of soda. Certain mineral waters, especially Carlsbad, are frequently of value in the treatment. [F. J. K.]

3.—Bland-Sutton in his first lecture on the surgery of pregnancy and labor complicated with tumors remarks that when an ovarian tumor occupies the pelvis and offers mechanical impediment to delivery, the fetus almost invariably dies and the following accidents may happen: (1) Rupture of the cyst; (2) rupture of the uterus; (3) rupture of the vagina; (4) excursion of the tumor into the rectum. Rupture of the uterus, he believes, is a somewhat exceptional accident under these conditions, while rupture of the vagina is an unusual accident when it occurs as a result of the efforts of the uterus alone. One case has been observed and recorded in which an ovarian dermoid obstructing labor had been pressed into the rectum and the wall of the bowel had become invaginated and the tumor, invested by the bowel, had been excluded through the anus. The common way in which nature overcomes the difficulty is by rupture of the cyst; if the fluid be sterile the results are not necessarily harmful, but when the tumor has thick walls and contains dermoid material the effects are often very grave. Today the choice of treatment of this condition lies between two methods: 1. In the early stage to push the tumor out of the pelvis and allow labor to be completed, and subsequently to perform ovariectomy. 2. To perform ovariectomy at once and then to accelerate labor by the use of forceps. It is now a well-attested fact that ovariectomy can be successfully performed even while labor is in progress, and that the operation in no way interferes with the contraction of the uterus. Single and even double ovariectomy can be successfully performed in the puerperium without in any way interfering with either the involution of the uterus or lactation. Therefore, it cannot be too strongly urged that when a puerperal woman known to possess an ovarian tumor exhibits unfavorable symptoms ovariectomy should be resorted to without delay. [W. A. N. D.]

4.—Osler makes a plea for more careful study of the symptoms of perforation in typhoid fever with a view to early operation. He mentions that the mortality of enteric fever is from 7% to 14%. Of the fatal cases 50% of the deaths are due to asthenia, 25% to perforation and 25% to hemorrhage and other accidents. Of the deaths which are due to perforation, he states that with early operation after an early diagnosis between 30% and 40% may be saved. Out of 11 cases operated upon in the Johns Hopkins Hospital since January 1, 1900, 5 recovered. The classical description of perforation as we see it is really the picture of the consecutive peritonitis. He gives a schedule with the view of aiding the resident physicians and house physicians in the study of early symptoms and signs of perforation in enteric fever. In this schedule he calls attention to pain, that we should be careful to note its onset and its locality; the state of the abdomen, its contour, the respiratory movements; the signs which are to be noted upon palpation, percussion and auscultation; and the data which may be gained by an examination of the rectum. The stools and the urine should also be carefully studied. The general condition of the patient is next referred to. Under this heading attention is directed to the facies, the pulse, the temperature, the respiration, hiccup and vomiting. The author next calls our notice to the constant leukopenia, and that it is of importance to note any rise in the number of leukocytes. He states that sudden pain is perhaps the most constant symptom of perforation, and concludes by stating that in a doubtful case of perforation the patient should be given the benefit of the

doubt and operation be performed. A surgical colleague should always be called as soon as this condition is suspected. [F. J. K.]

5.—Of 101 cases of litholapaxy, Harrison had a mortality of 6, and a recurrence of the stone to some degree in 23 cases. In most of the recurrent cases the patients suffered from enlargement of the prostate gland, or had pouched bladders, and were accustomed to use the catheter. Harrison thinks that these conditions are very often responsible for recurrences. Recurrence, however, does take place in people who do not suffer from any disease of the prostate or the bladder itself. In many of these the recurrence may be due to a passage of a stone from the kidney and this is as apt to occur after lithotomy as after lithotripsy. Great stress is laid upon the after-treatment of the bladder in cases of litholapaxy. This should be carried out after the patient passes from the hands of the surgeon into those of his regular medical adviser. So long as the urine remains abnormal or unexpectedly becomes so, as indicated by the appearance, smell, or microscopic examination, the bladder should be carefully attended to until such states are either explained or removed. Irrigation of the bladder should be regularly kept up, so long as the condition of the urine indicates that it is necessary. For this purpose boric acid or potassium permanganate may be used, two to four pints being used at a sitting. The catheter should be a large one so that any small particles may come away. When the bladder is sacculated it is well occasionally to wash out with the evacuator as after stone crushing. When the mucous membrane remains relaxed and spongy, as is evident from an excess of mucus in the urine, Harrison recommends that a solution of nitrate of silver (1 grain to 12 ounces) should be thrown into the bladder after irrigation. He thinks it a mistake to use nitrate of silver in the stronger solutions. Raney's theory of the formation of a stone by molecular coalescence is next discussed in detail. Harrison doubts the efficacy of drugs and waters to dissolve stone, but thinks that a number of these are useful to prevent the formation of a stone and a recurrence after removal. Hard waters produce an excessive amount of mucus in the urine and are hence condemned. Among the drugs mentioned as preventives are turpentine, sandal and copaiba. Boric acid, also, is highly recommended because of its antiseptic qualities. Erotropin possesses to a marked degree the valuable power of clearing the urine and keeping it so. The solution of nitrate of silver prevents molecular coalescence and hence lessens the tendency to the formation of stone. Harrison's paper is illustrated by the report of 6 cases. [J. H. G.]

6.—Guthrie reports a case of myasthenia gravis. The patient, a female, aged 23, a waitress by occupation, was admitted January 26, 1900, to the Hospital for Epilepsy and Paralysis, Regent's Park, London. The only point of interest in the family history is that an aunt suffered from epilepsy, and a sister of the patient had an attack of chorea. The present illness began very gradually a number of months before admission to the hospital. The first symptom was difficulty in speaking, owing to spasm of the jaw, as the patient says. This symptom was more pronounced towards the end of the day. The difficulty of speaking gradually increased and was followed by difficulty in swallowing. She had considerable trouble in swallowing liquids and solids. Upon admission it was noticed that there was paresis of the orbicularis oris and palpebrarum, also of the tongue, soft palate, and probably of the pharynx. She could not close her eyes and could not whistle. Ocular movements were not disturbed. The pupillary reaction was normal and there was no restriction of the field of vision. Speech was indistinct and deglutition was rendered difficult. The symptoms always increased in severity towards the end of the day. Only after exertion was actual loss of muscular power apparent. The reflexes, both tendon and superficial, were normal. There was no disturbance of sensation. With regard to the myasthenic reaction, the right biceps ceased to react to faradism in about one minute, while the left biceps required about a minute and a half. The patient gradually improved and in three months was sent home. The treatment consisted in rest and the administration of liquor strychninae. The patient was in fair health until June 15, 1900, when she suffered a severe relapse. All of the symptoms returned with increased severity. There were also weakness of the muscles of the neck and marked general fatigue. It became im-

possible for her to swallow liquids, and she was therefore fed with nutrient enemata. Death occurred on July 16, probably due to respiratory failure and gradual exhaustion. The post-mortem examination gave no clue as to the cause of this condition, and was as a whole negative. The author states that he believes that myasthenia gravis is due to a toxin which is probably elaborated within the body. He gives the theory of its origin in the muscles, but states that Dr. Bramwell, by an ingenious experiment, has shown that this is not the seat of origin. He also mentions that the origin may be due to disturbances of suprarenal bodies, or the poison may be formed within the spleen. He then gives the diagnosis of this disease, and mentions that out of 60 cases, 24 proved fatal. Complete recovery may follow. The author then gives a careful review of the points to be considered in the differential diagnosis between myasthenia gravis and hysteria, bulbar paralysis, diphtheritic paralysis, Landry's paralysis, multiple neuritis, and postinfluenzal neuroses. He mentions that the most important indication in the treatment is complete rest of body and mind. Drugs have proved useless in the management of this disease. [F.J.K.]

7.—Brown in an article entitled **ptomaine poisoning or perforation**, states that on November 19, 1900, he was called to see a woman, 27 years of age, who was in a state of unconsciousness, the eyes were open, pupils dilated, irregular movements of the eyeballs, and the temperature was 103° F. in the axilla. Upon examination the abdomen was found to be tympanitic. After an hour the temperature rose to 105° and the pulse was 140 per minute. In a short time she developed rigors and the temperature fell to 90° F. The extremities were cold, the skin was clammy, and the patient developed hallucinations with general nervous prostration, diarrhea and vomiting. Eighty six hours after the onset of the disease death occurred. From the history as ascertained from her friends, it was learned that she had partaken of 2 beef sausages 2 days before the onset of the illness. Three other persons partook of these sausages and 2 of them developed diarrhea and vomiting. The post-mortem examination revealed an exudation of lymph in the peritoneal cavity and the serous lining, the small intestines were intensely inflamed. The petechiae and ecchymoses were found in the duodenum and stomach, and the gastric mucosa was acutely inflamed. He states that the points of interest in this case are the sudden onset, high temperature, absence of muscular weakness and inflammation of the serous coat of the small intestine without apparent inflammation of the mucous coat. [F.J.K.]

8.—Thyne reports a case of **cerebellar hemorrhage presenting well-marked cervical opisthotonos and Kernig's sign** occurring in a man, 20 years of age. The patient gives an epileptic history, and was suddenly taken ill after partaking of a hearty meal. The onset was marked by vomiting. Six hours afterwards, there was marked retraction of the head, and the patient suffered from severe frontal headache. Kernig's sign was present. There was no motor paralysis, and convulsions and twitchings were absent. Tendon reflexes were exaggerated. Consciousness was not impaired. Upon postmortem examination, a subarachnoid serous effusion was found, also a thin layer of coagulated blood over the right occipital lobe extending down to the cerebellum, and the fourth ventricle contained a blood-clot. The lateral left lobe of the cerebellum was the seat of small hemorrhages. No evidence of meningitis was found. The author states that the case is of interest, because cervical opisthotonos and Kernig's sign were due to cerebellar hemorrhage, and not to meningitis. [F.J.K.]

9.—Lea records a case of **pelvic sarcoma with chylous ascites**, in which, after abdominal section and drainage, the tumor ceased to grow, and, 4½ years later, had shown no tendency to increase in size. The lacteal obstruction also disappeared, and the chylous ascites failed to reappear. Lea offers no explanation as to this remarkable occurrence, which has occasionally been noted by other operators. [W.A.N.D.]

1. State Care of the Insane. HENRY WALDO COE.
2. The Normal Declinations of the Retinal Meridians. GEORGE T. STEVENS.

3. The Relations of Scurvy to Recent Methods of Artificial Feeding. J. P. CROZIER GRIFFITH.
4. The Pathology of Intra-uterine Death. NEIL MACPHATTER.
5. A Simple and Accurate Method of Substitute Infant Feeding. HENRY DWIGHT CHAPIN.
6. A Clinical Report of the Use of Chloretone as a Hypnotic. A. A. STEVENS.

1.—Henry Waldo Coe discusses the **State care of the Insane** and deprecates the present method of crowding together insane patients as well as the system which the limits of State appropriations force upon those having charge of these patients. He believes that the appointments of physicians should be by merit and not influenced by politics. His idea is that the chief physician of an asylum should have the appointment of his assistants as well as full discretionary power in the management of the institution. He believes that the ideal method of treatment would be the **cottage-plan**. This would necessarily imply an increase in the number of attendants, yet the result of such treatment would certainly be more favorable to restoration of mental health in many cases. The care of the insane is a great burden upon the State, but the percentages of recovery under a liberal and thoroughly modern system would compensate for the additional expense. [T.L.C.]

2.—Stevens defines "normal declinations of the retinal meridians" as a deviation of the vertical, horizontal, or any given meridian of the eye from the corresponding meridian of external space when the line of regard of the eye is directed parallel to the median plane and in the horizontal plane, the head being exactly erect or, more technically, in the primary position. The definition is illustrated by an accompanying diagram. He employs the term "anomalous" in designating a normal declination in contradistinction to that resulting from paralysis, paresis, or insufficiency of one or more ocular muscles. Among the instruments employed for determining declinations there are mentioned the "clinoscope," and the "lens clinoscope." One of the first results obtained by the employment of the clinoscope after it had been shown that normally there existed for the vertical meridian a leaning out of about 1½° (while the horizontal meridian was supposed to exactly coincide with the real horizon), was the demonstration of the fact that when either of the meridians leaned that the position of the vertical and horizontal meridian leaned in corresponding directions and to an equal amount. Correction of declination is followed in a large number of cases by the relief of hyperphoria. He associates a number of symptoms which appeared to result from hyperphoria, with declination. The symptoms are, locally, dryness and smarting of the eyelids, with the sensation in them of "grit," as well as chronic hyperemia of the lids. Supraorbital pain is frequently complained of and careful observation in these cases will show, that while one brow is arched the other one is flattened against the eye-ball. Stevens emphasizes the fact that this supraorbital pain is not due to reflex disturbance, but is an expression of the muscular tension beneath in the effort to elevate or depress the brow. This is substantiated by the subsidence of the symptom upon the relief of declination. Variations in the contour of the brows and the declinations of the meridians are in relation to each other. The author calls attention to the amblyopia which is sometimes found in apparently healthy eyes without squint, and which is dependent on declination. When refractive errors exist or errors in muscular adjustment, the correction of these disturbances probably gives relief by lessening the difficulty in the management of the declination. Correction of declination can only be accomplished by **surgical intervention**. Operative procedures are peritenotomy, circumtraction (vertical or lateral) and extendo-contraction. By the latter operation a change in the direction of the meridians of two to three degrees or even more may be accomplished. The operation is described in detail, with accompanying illustrations of the instruments employed in its technic. [M.E.D.]

3.—J. P. Crozier Griffith reports **16 cases of infantile scurvy** under his care during the last 18 months. A study of these cases supports the generally accepted view that the **patented foods** often produce **infantile scurvy**, and some of them show that recovery may follow the withdrawal of these foods without other treatment. Griffith remarks that the cause of this action of these foods is in

doubt. It may be that they are so commonly derived from, or contain starch, or that they are deficient in certain ingredients. Two of his cases throw suspicion on barley water. These cases indicate also that the sterilization of milk has an undoubted power to produce scurvy, but it is a less prominent factor than the patented foods. It is seen that scurvy can readily develop on a diet of milk which is not long heated, or which is even raw. It is interesting to note that in some of his cases fruit juice may be given, and improvement noted, without any change in the food whatever. He concludes that, whereas there are classes of foods which are particularly apt to produce scurvy in infants, yet the individual element is remarkably present in this disease. [T.L.C.]

4.—Will be abstracted when concluded.

5.—Henry Dwight Chapin presents a simple, accurate method of substitute infant feeding. In preparing the infant food, it is necessary to have the milk bottled at the dairy, and kept at low temperature. He then dips off from 9 to 16 ounces from the top of the bottle, and then sets aside the milk bottle to avoid confusion. He advises this method rather than using a syphon. He then prepares dextrinized gruel in the following manner: Beat into a smooth, thin paste with a little cold water two heaping tablespoonfuls of wheat or barley flour; and a quart of boiling water, and boil the gruel for about 15 minutes. It is then cooled, and a preparation of diastase is added. He recommends that an aqueous solution of diastase be prepared at home by soaking malted barley grains in cold water. The gruel is stirred and kept warm until it becomes thin and watery. Dilute the top milk taken from the original bottle with the digested gruel and add sugar. The food for a young infant should contain from $\frac{1}{3}$ to $\frac{1}{2}$ of the 9 ounces of top milk. The food for an older infant should contain $\frac{1}{3}$ to $\frac{2}{3}$ of the 16 ounces of top milk. Sugar is added to make up for the amount lost in the dilution. He recommends that when the milk cannot be kept below 60° F., it will have to be pasteurized. When there is vomiting of food, the digested gruel may be fed temporarily, and a top milk, poorer in fat, used for making up the next feeding. [T.L.C.]

6.—A. A. Stevens has used chloretone in 50 cases, in which sleeplessness was an important symptom. Chloretone is trichlor tertiary butyl alcohol, a compound formed by the addition of caustic potash, with equal weights of chloroform and acetone. It possesses valuable hypnotic and local anesthetic properties. Stevens concludes that in chloretone we have a safe hypnotic of moderate power, which rarely gives rise to unpleasant after-effects, but of which a toleration is quite rapidly acquired. The drug is especially adapted for use in cases of insomnia unattended with pain, high fever, or pronounced nervous excitement. The dose is from 10 to 20 grains. It may be conveniently administered in the form of powders or compressed tablets. [T.L.C.]

Medical Record.

February 23, 1901. [Vol. 59, No. 8.]

1. The Necessity for a More Careful Investigation as to the Cause of Outbreaks of Infectious Diseases. ALVAH H. DOTY.
2. A Method of Fixation for Loose Kidneys. ROBERT T. MORRIS.
3. Convulsions with Scarlet Fever, and the Report of a Very Severe Case with Perfect Recovery, and Important Deductions from the Treatment. HERMAN E. HAYD.

1.—Alvah H. Doty, of New York, discusses the necessity for a more careful investigation as to the cause of outbreaks of infectious diseases. Dr. Doty's wide experience as Health Officer of the Port of New York qualifies him to speak with authority upon this subject. In the first place he states that the theory of contagion from clothing worn by well persons is in the vast majority of cases found to be unsupported. Experience teaches that epidemics are most frequently carried by mild, ambulant, or convalescent cases, thence the necessity of the recognition of such cases. Upon the discovery of a case of infectious disease it is the first and most important duty of the health officer to ascertain, if possible, its origin. When the physician is called to such a

case, he should at once require that all the clothing of the infectious case be brought together; not one article should be missing. This material should be subjected to a thorough and immediate disinfection, and steam should be used for this purpose. In marine sanitation the crews and passengers from an infected port should go through a most rigid examination. For the past 3 years Doty has required that all of the passengers and crews arriving on vessels from infected ports shall have their temperature taken before being released from quarantine. Many cases of yellow fever and other contagious diseases have been detected in this manner. [T.L.C.]

2.—Robert T. Morris details a method of fixation for loose kidneys. In this operation a flap of capsule, including the larger part of the mesial surface of the kidney, is incised with a scalpel and the flap of capsule then stripped up from the parenchyma, but remaining attached to the convex border of the kidney. The flap of capsule is drawn through a slit in the psoas muscle or the quadratus. This brings the parenchyma also in contact with the psoas or quadratus fascia, where it forms a firm connective tissue attachment. The operation avoids the necessity of passing sutures through the parenchyma of the kidney. [T.L.C.]

3.—Herman E. Hayd reports a case of scarlet fever with severe convulsions, followed by recovery. Copious clinical notes of his case are given, and the writer concludes with the following deductions: Convulsions may occur when least expected, and every case of scarlet fever should be closely watched for many weeks. The frequent examination of the urine should include the calculation for urea. Mere specific gravity is not a sufficient index as to the amount of urea eliminated. Albumin need not be present, or only a trace may be found, yet convulsions may occur. The increase in the albumin will generally be noted after the convulsions occur. Milk is the ideal food, but if it cannot be well digested, the author advises that no food should be administered for days by the stomach, simply an abundance of water and the patient nourished by nutrient enemata. In any severe case of convulsions very small amounts of nourishment should be given at one time and the urea equivalent must be determined. He recommends hypodermoclysis to the amount of from 2 to 3 pints. Enteroclysis is advised, with the water at a temperature of 80°, once or twice in 24 hours, if much fever be present. Strychnin, digitalin, and brandy are recommended as heart stimulants. [T.L.C.]

Medical News.

February 23, 1901. [Vol. lxxviii, No. 8.]

1. The Value and Accuracy of the Röntgen Method of Diagnosis in Cases of Fracture. CHARLES LESTER LEONARD.
2. Pararyngeal Adenoids and Hypertrophied Tonsils. J. H. WOODWARD.
3. The Sustaining Treatment of Typhoid Fever, with Special Reference to the Use of Hypnotics. A. H. BUCKMASTER.

1.—Leonard calls attention to the various conditions in which the Röntgen ray is useful for diagnosis, and says that (1) many fractures that were considered rare exist in a much greater proportion than was suspected; that the functional loss which was supposed to result from a traumatism or sprain, and was termed traumatic arthritis, or a bad sprain, is often in reality the result of an undetected fracture which it is impossible to diagnose by other methods of examination. The Röntgen ray is useful for (2) detecting unsuspected fractures and multiple fractures when only one was suspected; (3) exact line of the fracture; (4) to guard against the production of deformities, such as overlapping and shortening in oblique fractures; in transverse fractures, angular deformities; in spinal fractures, a rotation of one fragment on the other, while in fractures involving joints a restriction of motion may result from malposition of the fragments, or the interference of motion due to excessive callous formation; (5) accurate information is obtained without manipulation; (6) to render the exact coaptation of the fragments more certain and easier or determine the impossibility of complete reduction without operative interference; (7) accuracy of the setting and the efficiency of the fixation apparatus or other methods of treatment. [T.M.T.]

2.—Woodward divided the symptomatology of pharyngeal adenoids into: 1. Symptoms common to all adenoids, viz., hyperplasia of the lymphoid tissue in the vault of the pharynx, chronic congestion of the submucous bloodvessels of the inferior turbinated body; a more or less profuse, mucopurulent discharge. 2. Symptoms dependent upon the size of the adenoid, viz., alteration of the voice, as if the patient was suffering from a cold in the head; mouth breathing; snoring and choking in sleep; general malnutrition; deafness; chronic headache and mental dulness. 3. Occasional accessory symptoms including asthmatic seizures; habit (facial) chorea; epileptiform attacks. To these may be added the state of deaf-mutism as one of the consequences of adenoids in infancy, for adenoid vegetations occur in the earliest months of infancy. Adenoid vegetations are very rarely seen in persons over 20 years, and retrogressive changes of the hyperplasia take place during adolescence if left alone, although this is not the advised course. There seems to be no doubt that the most effectual treatment is their removal, although in special cases the application of tincture of iodine and nitrate of silver may be sufficient. The author also gives the following symptoms of hypertrophy of the faucial tonsils; alteration of the voice in which the tone is muffled as if patient were holding something in his mouth; snoring and choking in sleep; excessive secretion of mucus in the throat; frequent attacks of acute catarrhal inflammation in the throat and follicular tonsillitis; chronic enlargement of cervical lymphatic glands; mouth breathing; deafness; general malnutrition. This condition is generally found before the age of puberty, especially between the ages of 3 to 10 years. The treatment depends upon the degree of hypertrophy and the symptoms present. If marked they should be removed, even if the tonsils are not markedly enlarged, during period of quiescence or reduced in size by the application of acute cautery or astringent alteratives. [T.M.T.]

3.—Buckman sums up his treatment of typhoid fever with special reference to the use of hypnotics, and his advice to physicians is as follows: 1. Ascertain how much food is necessary, and whether patient has had enough food, water and fresh air in the 24 hours. 2. Do not allow the patient to wear himself out by continued high temperature or by lack of sleep. The amount of sleep in the 24 hours should be recorded. 3. Examine the urine frequently, and ascertain the daily quantity; also keep posted as to movements of bowels and condition of skin. [T.M.T.]

4. Dysbasia Intermittens Angiosclerotica (Intermittent Lameness of Vascular Origin). JAS. J. PUTNAM.

2.—Dysentery is responsible for the highest mortality among our troops in service in the East, but even this statement does not give any adequate idea of the gravity of the disease. Dysentery in the **Philippine Islands** is responsible for more permanent disabilities than all the rest of the diseases combined. A complete permanent recovery in the islands is the exception to the rule. There were 132 deaths from dysentery at the First Reserve Hospital up to June 1, 1900. Ninety-eight of these cases of dysentery came to post-mortem. Of these, 66 were found to be amebic dysentery, 20 acute dysentery, and 12 subacute dysentery. In the great majority of cases among our troops there was a history of drinking polluted or uncertain water. Malaria is the most frequent complication of dysentery in the Philippine Islands. Typhoid fever and amebic dysentery combined occurred twice and acute lobar pneumonia occurred once in this series of 66 cases of amebic dysentery. There were 2 cases of active and quite extensive pulmonary tuberculosis. As will be seen from reference to the classification of the 98 cases autopsied, amebic dysentery is the most common type,

and it is responsible for many more deaths than all the other types combined. Whether the ameba coli is primary or secondary, we have the strongest evidence that it is certainly a very important etiologic factor. In several of the cases of acute dysentery that came to autopsy a bacillus apparently identical with that described by Shiga and by Flexner was found in culture. [J.M.S.]

4.—Putnam reports the case of a man who suffered from **dysbasia intermittens angiosclerotica**, first described by Charcot, in 1854. The patient was an active and able business man, a gentleman of 70, with a remarkably good record for soundness of constitution, temperance of habits, and freedom from disease and exposure. He was without signs of nephritis, diabetes, cardiac, or arterial disease, unless an attack of sudden giddiness in which he was once precipitated forcibly and suddenly from his chair to the floor was due to a cerebral lesion of arterial origin. The symptoms of chief interest in the present connection first showed themselves, 2 months before the author's examination, in the form of an intense sense of muscular fatigue in the legs, amounting almost to pain, which recurred every time the patient walked more than $\frac{1}{2}$ -mile, but quickly passed away with repose. Since then this condition has remained substantially unchanged. The pain is usually felt first in the calf, generally that of the left leg before that of the right, and then spreads upward, omitting the knees and centering in the neighborhood of the hips. The patient then feels, although a man of great resolution, as if he must stop, and that if he went on his joints would grow rigid and he could not move. After a rest, or on waking in the morning, he feels perfectly fresh and "as well as ever in his life." Mental work causes no fatigue, and he is singularly free from neuro-rasthenic symptoms of all sorts. The treatment consisted of galvanism, which was carried through the length of the limb with the foot resting in a tub of warm water. Then faradism was used in a similar manner. Finally, a deep vessel was obtained so that the legs could be immersed up to the knees in water, and this was charged with solutions of artificial Nauheim salts of increasing strength, the temperature of the water being at the same time lowered, day by day, or week by week. Good cutaneous reactions were secured, but the most that can be said for the success of the treatment is that the patient grew no worse during the time of its use. The author believes that a vascular spasm is perhaps the best explanation of the pathology of the disease. [J.M.S.]

1.—Vaughn and Cooley, in an article outlining the **nature and action of the bacterial toxins**, present the following theory: That specific poisons constitute a part of bacterial cells, and are formed within the microorganism itself. They also state that the pathogenic principles of a given bacterium are dependent upon the diffusibility of the toxin, the character of the poison in the cell, and the permeability of the cell wall. The authors mention that they gained little information from the literature upon this subject; they, however, refer to the researches of Buchner and Pfeiffer. The

authors have carried on a number of experiments with the bacillus coli communis, and have reached the following conclusions: The colon bacillus, in a virulent form, contains a toxin within the cell. This poison is fatal to guineapigs, weighing from 200 to 300 grams in the dose of 1 milligram. Aqueous extracts of this microorganism grown upon agar are inert. The bacillus possesses a great resistance to heat, dilute acids, and alkalies. Artificial gastric juice will digest the cell-wall, but does not alter the toxin. When the poison is obtained in this manner, it was found to be insoluble, or but slightly soluble in dilute acids, but more readily soluble in dilute alkalies, and slightly soluble in water. The toxin gave the ordinary proteid reactions, and finally it was found that the toxin was not destroyed by boiling. [F. J. K.]

2.—In an article on the **management of consumptives** by S. Solis-Cohen the author states that drugs play a secondary part, and that the disease is curable as a result of the natural power of recovery. He carefully outlines the hygienic management. He gives the progress of pulmonary tuberculosis, dividing the disease into a primary stage, a secondary or bacillary stage and a tertiary stage. In the final stage various microorganisms, principally streptococci and staphylococci, produce degenerative changes and markedly influence and modify the course of the disease. He mentions the important drugs which are to be used as nervines, digestants, hematinics, eliminants, and those acting upon the circulation. He outlines the uses of the iodine group, and the creosote group. He then mentions the drugs which influence the cough, the fever, night-sweats, diarrhea, outlines the treatment of hemorrhage and states the uses of inhalants. He concludes by saying that hygienic and nutritional measures are to be preferred to the use of drugs. [F. J. K.]

3.—Holmes, in an article on the importance of early diagnosis of tuberculosis, classifies the disease into three stages: (1) The pretubercular stage, which is associated with a weakened state of the system and therefore furnishes a congenial soil for the tubercle bacillus; (2) the stage of tubercular formation; and (3) the stage of destructive tissue changes. The cog-wheel respiration he believes is an important sign in the recognition of early tuberculosis. He also refers to the value of observing the temperature, and he believes that a subnormal temperature is one of the earliest signs. The value of finding the bacillus in the sputum, from the standpoint of diagnosis and future treatment, is overestimated, as it only appears with breaking down of tissue. The tuberculin test is mentioned as being of value in the early stages of the disease. [F. J. K.]

4.—Richardson's first case is one of **sinus thrombosis** in a man 60 years of age. In this case the mastoid antrum was found filled with a nasty, offensive pus which was thoroughly cleaned out. The sinus was then exposed throughout its whole length and its walls found to be gangrenous. The vessel was opened and found filled with broken-down blood clot which was removed until circulation was restored from above. The jugular vein was then exposed in the neck; it was collapsed and contained some organized blood clot. The vessel was ligated and removed. The patient was in an intensely septic condition before operation and died of sepsis 26 hours after operation. The second case is one of **infective thrombosis** in a man aged 25. This patient had all the symptoms of mastoid disease and also had a cellulitis of the cervical tissues below the mastoid. The ordinary mastoid operation greatly relieved this condition; the patient's temperature became normal and remained so for several days. In about 2 weeks, however, the temperature began to rise and pus formation showed itself in the anterior temporal region. This was freely liberated by incision, the pus being found between the temporal fascia and the periosteum and showing direct communication with the mastoid cells. At one point just above and in front of the zygoma there was a carious perforation of the outer table. Upon careful exploration of this condition it was found that the patient was suffering from a decided case of osteomyelitis, the probe passing readily for some distance between the outer and inner tables of the skull. A large portion of the outer table was removed. The patient did well for four or five days when his temperature again rose, due to a collection of pus in the occipital region, but subsided again upon free opening. About a week later the patient had sweat, chill and a rise of

temperature, with evidence of involvement of the sigmoid sinus. The sinus was exposed, found to be filled with broken-down clot which was removed until a return circulation was had from below, but no return circulation could be obtained in the other direction, although exploration was carried nearly as far back as the torcular. The patient improved a great deal after this operation, the temperature falling, his general condition appearing better, but within a few days symptoms of extension of the infection returned and the patient died. No autopsy could be obtained. Case number three is that of a man aged 63 years, who had suffered for some weeks with a **suppurating ear** and who later developed symptoms of **cerebral abscess** involving the speech center. The mastoid cells were not found involved at the operation and an exploration of the temporosphenoidal lobe through a trephine opening, made one inch above the external auditory meatus, revealed no abscess, although it was felt sure at the time of the operation that such was present. The patient died and at the postmortem a small abscess about the size of a hickory nut was discovered on the mesial side of the uncinate convolution. Richardson thinks that in his exploration the probe must have passed through this abscess cavity, but that the pus was too thick to flow. In cases of **sigmoid thrombosis** prompt operation is urged as soon as the diagnosis is made. Richardson urges the careful consideration by the general practitioner of symptoms indicative of extension of the disease to the sinus. The occurrence of a chill, a high temperature and a sweat are symptoms of extreme gravity and should suggest involvement of the sinus. In operations for this condition he thinks that ligation of the jugular vein should be done, even though a return circulation may be had. Richardson thinks that one of the early symptoms of **cerebral abscess** from disease of the ear is an alteration in the general demeanor of the patient, such as irritability, moroseness and attacks of semihysteria. To these should be added also some form of aphasia. [J. H. G.]

5.—Knapp shows the most frequent age for **suppurative tympanomastoiditis** to be the early years of life, particularly the first year. He gives as a cause for this the short and patulous eustachian tube at this age, and the fact of the great prevalence of diseases, particularly adenoids, in the nasopharynx of children. The short and patulous tube also explains the quick and permanent disappearance of abscesses of the middle ear in children. In operations upon the mastoids of children it is recommended that the incision be made carefully, and layer by layer, because of the soft condition of the bone at this age. [J. H. G.]

6.—Calhoun discusses **disease of the mastoid cells** as it occurs in the South. He does not think that middle ear suppurations are as prevalent in the South as in the colder climates. During the past winter he has observed the disease to be of a mild type and unusually free from cerebral and other complications. He has found it as frequent in adults as in children, but very seldom in the negro race. He also calls attention to the possibility of serious mastoid disease without marked outward symptoms, and also to the occasional occurrence of mastoid disease without apparent middle ear involvement. He has not found it necessary in the treatment of these cases to pursue the radical measures of Stacke. [J. H. G.]

7.—In an article by Spalding the **differential diagnosis between chickenpox and smallpox is given**. The author states that he has seen a number of cases of chickenpox in adults and he gives the report of a case which occurred in a male 22 years of age. The eruption in this case appeared first on the body and then on the face, limbs and hands. There were no prodromal symptoms. The eruption consisted of vesicles which later developed into pustules or dried scabs. The eruption was very superficial. He mentions that the most experienced diagnostician may sometimes be puzzled in the diagnosis of varicella from variola. There appear 3 illustrations showing the character of the eruption in chickenpox, also 3 showing the eruption in smallpox. He believes that the eruption in smallpox always involves the cutis vera, while in chickenpox the lesion involves only the outer layer of the skin. He emphasizes the importance of the prodromes which occur even in the mild cases of variola, and they are absent in varicella. [F. J. K.]

1. Ventral Hernia Following Abdominal Section. B. BRINDLEY EADS.
2. On Traumatic Keloid of the Median Nerve, with Observations upon Absorption of Silk Sutures. OTTO G. I. KILIANI.
3. An Intestine Holder. Devised for Facilitating the End-to-End Suture of Intestine. EDWARD H. LEE.
4. Laryngectomy under Eucaïne Anesthesia, with Remarks on the Technic of the Operation. GWILYM G. DAVIS.
5. Double Ureter. Report of a Nephrectomy Done upon a Young Child with this Condition Present. JOHN EDWARD SUMMERS, JR.

1.—In ventral hernia following abdominal section Eads thinks that at least 15% of all cases of laparotomy if examined five or more years afterward will present evidences of hernia. Coley has pointed out that relapses after operation for ventral hernia take place in more than one half of the cases. Eads discusses the anatomy of the abdominal wall in detail, laying particular stress upon the nerve-supply of the muscles. If a nerve supplying muscle is severed the muscle loses its contractility, it becomes wasted and weakened and the intraabdominal pressure produces stretching, and finally hernia. Close suturing and accurate approximate of like structures will not prevent this, nor will prolonged stay in bed. "Intact, innervated muscular fiber is the only safeguard against hernia." He urges that all muscular section should be made parallel with the nerves if possible. The vertical incision over the rectus with separation of the muscular fibers, so highly recommended, is a failure because the inner portion of the muscle is deprived of its motor nerve-supply. Incision to the left of the rectus muscle parallel to and a little below the costal arch gives ready access to the cardiac end of the stomach and permits a separation of the fibers of the internal oblique and of the motor nerves, besides giving a sphincteric action to the wound. The great advantage of the McBurney incision for appendicitis is that it permits the separation of the nerve fibers instead of their division. The author suggests a lower incision than that of McBurney, slightly concave with the concavity upwards. Incision in the linea semilunaris is condemned because of the resulting paralysis from the division of the nerves supplying the rectus. An incision through the rectus is but little better. In making an incision in the median line he insists that it shall be accurately placed between the two recti muscles. Incision through the umbilicus should be carried to the left in order to avoid the suspensory ligament of the liver. In discussing the treatment of ventral hernia he says it is necessary to excise the redundant and atrophic tissues, bringing into the wound-area as much muscular fiber as possible. [J.H.G.]

2.—Kiliani reports a case of division of the median nerve by glass. The nerve was sutured 3 or 4 weeks after the accident, small bulbi being excised from the distal and central end. The wound did not heal primarily, and there was no improvement in symptoms. Six weeks later, when he first saw the case, a good-sized neurofibroma was found which interrupted completely the conduction of the nerve. The tumor was again excised, nerve ends sutured with catgut, primary union followed with immediate restoration of sensation, and very soon that of power. Three months after this operation the scar on the skin showed a keloid, and a small tumor was felt in the nerve. One year after the operation the tumor had disappeared and the hand was useful for all practical purposes. Kiliani has been unable to find a case cited where neurofibroma with no indication of sarcomatous degeneration had occurred after extirpation. He believes the growth of the nerve can be properly called a keloid. At the second operation he found the silk suture employed at the first operation undergoing absorption as is shown by the microscopic sections which illustrate his article. [J.H.G.]

3.—Lee describes and illustrates the use of a new intestinal anastomosis appliance. It is a metal instrument adjusted to fit any size of intestine, and when the anastomosis is completed it is made to fold upon itself and can be withdrawn through a very small opening. The illustrations explain its use. [J.H.G.]

4.—Davis reports the case of a man, 46 years of age, suffer-

ing from a carcinoma of the larynx, with no glandular involvement and in which he performed a total laryngectomy with eucaïne anesthesia. No preliminary tracheotomy was done. The patient but once winced with pain and then when the superior laryngeal nerves were divided. The growth caused considerable stenosis and respiration was difficult. The trachea was divided and brought forward, and then the larynx removed by careful dissection and the wound closed without drainage. Patient had no shock. Seventy-five minims of a 1% solution of eucaïne B were used during the operation. On the third day patient could speak in a whisper and was able to swallow small amounts of liquid. His temperature rose, he had considerable cough, and he died on the sixth day. Postmortem examination showed intense congestion of tracheal and bronchial mucous membrane as well as of kidneys, liver, and spleen. The wound above trachea healed primarily. About the tracheal opening were a few drops of pus. Streptococcus growths were obtained from the various organs. Davis thinks the main objection to local anesthesia is that it prolongs the operation. The Trendelenburg position was not found necessary in the operation. The subsequent coughing produced considerable irritation about the tracheal opening and necessitated the cutting of some of the sutures. Davis thinks this a great objection to the mode of operating, and attributes to it the infection in his case. He agrees with Delaven that preliminary tracheotomy is a better procedure. He thinks the leaving of an esophageal tube in the wound is probably unnecessary, and that the upper wound can be completely closed. [J.H.G.]

5.—Summers discusses first the several varieties of anomalous ureters and then reports the following case: A child, aged 2½ years, suffered from a tumor of left kidney, which could be easily palpated. The urine contained tubercle bacilli. Nephrectomy was done, and it was found that the organ possessed two ureters, proceeding from separate pelves. The upper tube was the larger, and the seat of tubercular disease, while the lower and smaller was normal. He thinks that the ureters opened into the bladder separately, or else both would have been diseased. The patient recovered from operation, and when last heard from was in good condition. He remarks on the difficulty of using a segregator in ureteral catheterization in such a case. [J.H.G.]

1.—Every practitioner of medicine must have some dental knowledge. For in spite of the fact that there are specialists for each separate part of the body, every physician should know the correlation of the different parts, no matter what specialty he practises. Especially since the development of bacteriology, do we realize how splendid an incubator the mouth makes. Even malignant endocarditis may come from defective teeth. Williamson suggests a short dental course for medical students. The student should be taught how to examine the teeth, to find cause for neuralgia. To show the lack of this knowledge in older physicians, he reports a number of cases. The student should also be able to recognize the milk teeth, and to differentiate them from the permanent teeth. He should, besides, know enough to advise a visit to the dentist when necessary; or to say whether a tooth should be extracted or not. To help to make this clear to students, Williamson suggests the use of dental models in the dissecting room. Besides, every stu-

dent should have practical experience in extracting teeth, and a knowledge of the correct instrument to be used in every case. And the students should know how to administer nitrous oxid gas. With such an education the result will be a hearty cooperation between dentist and doctor, followed by the amelioration, or, better still, the prevention of dental decay. [M.O.]

2.—In this article James discusses the **prognosis and treatment of phthisis**. The prognosis depends upon 5 things: The family history, not only the occurrence of tuberculosis, but also of other constitutional diseases; the conditions which have led to the development of the disease; the general condition of the patient; the amount of lung tissue involved; and the complications, such as laryngeal or enteric tuberculosis, etc. The main object in the treatment is to put the patient far from civilization, where air is pure, where freedom of movement, of body, and of lungs is absolute, where sunlight is abundant. Yet those with very extensive lung disease, those with very slight recuperative power, and those who cannot leave home, will not be benefited by this primitive living. For these James advises the sanatorium as the best place for treatment, at least until the patient has learned how he should live. The correct food, cold bathing, menthol, or codein for the cough, morphin for hemoptysis, quinin, antipyrin, etc., and ice for the fever, and cod-liver oil, form the most necessary modes of treatment. [M.O.]

3.—Wallace reports 3 cases of this rare affection. The first case, a man of 21, went to South Africa 4 years ago. Two years later he had **hematuria** which has continued since. Treatment has been of no avail. The second case, a South African of 21 years, too, had had **hematuria** for 9 years. He relates that all the boys at school passed red urine. At 15 he had renal colic. Upon diluents and salol, he improved. The third case was a native of Natal, also 21. He had no symptoms but **hematuria**. In all 3 cases, **ova of the bilharzia hematobia** were found in the clots in the urine. They were absent when the urine was clear. Only youths and young adults were affected. Salol alone seems to do good. [M.O.]

4.—After a review of the literature, Douglas sets forth the method pursued by him in investigating **cystitis**. Cultures were made at once, either after catheterization with a sterilized catheter, or from the last urine to flow, collected in a sterilized test-tube. Of the 20 cases of cystitis examined, only 3 occurred in women. Pure cultures of the bacillus coli communis were obtained in 12 cases, associated with other microbes in 2 cases. In 3 cases the staphylococcus grew alone, in 2 cases the tubercle bacillus alone. After a description of his experiments upon animals and an account of the characteristics of these colon bacilli, he concludes that the bacillus coli communis is met with in the great bulk of cases of cystitis, and is apparently the cause of the disease; that the microorganism may be present in the bladder for long periods of time without causing cystitis; that it may supplant other microbes, rather than be the initiating cause of the cystitis; that its marked polymorphism and pathogenicity account for the conflicting opinions regarding its identity and rôle in cystitis, and that no one reaction enables it to be certainly recognized, but that cultivation upon several media is needful. [M.O.]

5.—Borrowman reports the case of a boy, aged 9 years, who had measles and pertussis a year previous. With other boys he had for some weeks practised standing upon his head, in which position he could stay about a half hour. Headache and vomiting occurred, followed by 6 weeks of almost constant sleeping. Whenever he tried to sit up, he felt tired, and lay down at once. The muscles of the arms and legs had wasted considerably. His heart's action was very feeble. Under digitalis he improved immediately, and recovered wholly in four weeks. Borrowman considers the condition due to passive congestion from the inverted position, and not to tubercular meningitis, the only other possible explanation of this strange case. [M.O.]

6.—After a short exposition of the subject, Rose reports a case of **pseudohypertrophic muscular paralysis**, in a boy of 9½ years. Two years ago he began to be lazy. Then he had difficulty in rising, and soon became helpless. Lordosis was marked when he attempted to stand, and he could not stand alone, even with his feet wide apart. His method of rising from the floor is beautifully shown by

photographs. There were great muscular weakness; enlargement of the muscles of the calf, etc., with wasting of the muscles of the trunk, etc.; loss of the kneejerk, with diminution of other reflexes, and hyperesthesia to pain. Sections of the biceps and gastrocnemius show a great increase in the connective tissue, while the muscle fibers appear to be comparatively healthy. [M.O.]

7.—Dewar reports a case of **eclampsia** in a woman aged 28, in whom convulsions occurred without warning, at the sixth month of pregnancy. Ten convulsions occurred. There was no albumin in the urine. Four days later she had 7 more convulsions, and albumin was found in the urine. Three more convulsions followed 4 days later. Chloral and the bromids were given. Edema and varicose veins existed in both legs. Three months later the baby was born at term in excellent condition. At this time albumin was absent from the urine. As there was no cause or suspicion of epilepsy, he believes the case to have been **true puerperal eclampsia**. [M.O.]

Berliner klinische Wochenschrift.

January 14, 1901. [38. Jahrg., No. 2.]

1. Diphtheria. TH. ESCHERICH.
2. Gallstones. RIEDEL.
3. The X rays in Practical Medicine. H. KÜMMELL.
4. The Modern Efforts at Colonization and the Adaptability of Europeans to the Tropics. F. HUEPPE.
5. Concerning Succussion of the Kidneys. S. GOLDFLAM.

1.—The author extensively reviews the history of **diphtheria** from the time of Aretæus and Aëtius to the present century. Each epoch of diphtheria is considered and, especially, the researches of Bretonneau. The facts upon which the etiological significance of the diphtheria bacillus is based, are the following: 1. The constant presence and the great quantity of bacilli in all true cases of diphtheria (Bretonneau). 2. The absence of the bacillus on the mucous membrane of healthy individuals. 3. The specific pathogenic influence upon animals. 4. The production of the characteristic paralysis caused by the toxin of the bacillus. The older authors seem to have neglected the toxic effect of diphtheria upon the circulatory apparatus. Of great historical note is that epoch in medicine during which the characteristic symptoms of diphtheritic nephritis, its pathological anatomy, and the degenerative changes in the peripheral and central nervous system as well as in the muscles were established. The greatest transformation, however, took place in the therapy of diphtheria. The results obtained in the past 6 years show the astounding reduction of mortality due to the introduction of antitoxin. [M.R.D.]

2.—Will be abstracted when completed.

3.—Kümmell describes the **value of the x-rays** in practical medicine. In addition to their value for the detection of foreign bodies they have become of special service in military surgery. Pathological dilatation of the esophagus and stomach may be detected by the Röntgen rays. Both dilatation and stenosis may be made apparent by inserting into the organ either in bulk or in gelatine capsules some metal salt like bismuth, which on account of its impermeability to the x-rays reveals the existing conditions. Sounds may be also employed in connection with the x-rays in dilatation of the esophagus, as well as in gastric dilatation if the sound lies against the wall of the esophagus or the greater curvature. Foreign bodies in the intestinal tract may also be located by means of the x-rays as well as Murphy buttons and foreign bodies introduced for therapeutic purposes. The x-rays are of value when there are suspected pathological concretions, although up to the present time gallstones have been detected but twice by this means. Vesical calculi can generally be easily detected by the x-rays. The facility with which these foreign bodies can be detected varies according to the chemical constituency of the concretion. Concretions composed of urates and oxalates are less translucent than phosphatic calculi. Both incrustated as well as non-incrustated bodies, hairpins, etc., are easily demonstrable by means of the Röntgen rays. Considerable progress in the detection of renal calculi has also been made, and here also the thickness of the soft parts as well as the translu-

gency of the concretion renders its detection more or less difficult. The triumphant success of the x-rays in medicine is well known to have been due to the detection of **fractures, luxations, and diseases of bone.** Röntgen-rays have been of great value in diagnosing and treating congenital luxations of the hip. The differential diagnosis between congenital luxation and coxa vara is presented in an interesting manner by the x-rays. Syphilitic, tuberculous and osteomyelitic thickening and deposits in the large and small long bones are not difficult to recognize by means of the x-rays, and it is interesting to observe how under treatment a tibia that before medication appeared as a narrow shadow upon the radiograph, gradually increases in volume. Similarly, small pathological changes, such as tuberculous deposits, may also be diagnosed. Among the tumor-formations large, broad osteosarcomata are characteristically portrayed by the x-rays. Nothing of account has yet been attained in detecting other tumors of the body by this means, as the contrast of individual tissues is not sufficient to be of diagnostic value externally. The shadows of the liver and kidney as well as the convolutions of the fetal gut may be plainly seen, but less so in the adult. Fecal masses are easily recognized. Chemical substances introduced from without for therapeutic or diagnostic purposes, especially the iodine compounds, can also be plainly seen. Iodoform-glycerin injected into tuberculous joints remains there for a long time and is absorbed slowly. Here the Röntgen picture teaches us that it is not necessary to leave a great amount of this mixture in a joint, as small quantities being also slowly absorbed, fully meet the therapeutic requirements. Iodoform-glycerin injected into fistulous tracts is of diagnostic value in that it penetrates to the bone and permeates extensive sinuses. Characteristic results have been obtained in the recognition of myositis ossificans. **Arteriosclerotic changes** in the bloodvessels yield very plain x-ray pictures. Considerable progress has been made in observing the intrathoracic changes. The author states that the dilated lungs of emphysema, and the lungs in pleurisy and empyema were plainly seen by the x-rays and a pneumothorax which clinically could not be established with certainty was diagnosed without a doubt by means of the Röntgen picture. Lung cavities are easily detected. Peribronchial changes appear as sharply defined nodules of variable size. The shadows of the heart, aorta, and aneurysms as well as mediastinal tumors have repeatedly been employed for diagnostic purposes. The employment of the x-rays for therapeutic purposes has yielded excellent results in the treatment of **lupus.** It is to the treatment of skin diseases that the therapeutic efficiency of the x rays has been principally confined. Other skin diseases that have been successfully treated by this means are chronic eczema, vascular nevus, hypertrichosis, favus, and sycosis. Considerable has been attained since 5 years by this epoch-making discovery of Röntgen, but much more will be required during the present century. [M.R.D.]

5.—Goldflam in addition to bimanual examination and ballottement also employs the following method: While the patient stands with the body bent forward and exposed, the examiner places the ulnar side of the clenched fist against the lumbar region and performs a series of mild thrusts, which in the healthy individual are absolutely painless but which give rise to pain of more or less intensity in certain renal affections. In nephritis there is no pain, but on the other hand there is in nephrolithiasis, pyelitis, tuberculosis, abscess, tumors of the kidney, in short all those conditions which require surgical treatment. The author states that he considers this method of procedure of use, but only as an accessory to the other important methods of examination. [M.R.D.]

1. Remarks on Tuberculosis of the Female Genitals and Peritoneum. A. SIPPEL.
2. Vaginal and Abdominal Section in Tubercular Peritonitis. G. BAUMGART.
3. A Case of Hydrocephalus with Recovery. H. NEUMANN.
4. A New Sensitive Test for Sugar. E. RIEGLAR.
5. Contribution to the Study of the Renal Function. L. LIPMAN-WULF.

3.—Neumann reports the case of a child 5 months old that was brought to the clinic with marked hydrocephalus. The increase in the size of the head had apparently occurred chiefly within 3 weeks. There was a distinct history of syphilis. It was therefore a very satisfactory case for treatment, both because it was syphilitic and because the hydrocephalus was of very recent occurrence. It was put upon potassium iodid in large doses (taking in 9 months nearly 2½ ounces). There was rapid improvement after the first few days of treatment, and the improvement continued. At the end of 9 months the child seemed practically well. Somewhat over a year after the treatment was begun it was reported that the child's general development, both physical and psychic, seemed perfectly normal, and the head showed no abnormalities. [D.L.E.]

4.—The test recommended is to take about 20 drops of urine in a test tube, add a small amount (about 1/10 gram) of pure hydrochlorid of phenylhydrazin, about 1/2 gram of crystallized sodium acetate, 2 cc. of water. Heat over a flame until it boils, then add 10 cc. of a 10% sodium hydrate solution, inverting the tube five or six times and standing aside. After a few seconds there should be a striking reddish violet color. The color should be looked for by holding the test tube up to the light and the whole fluid should be colored, not merely the deposit upon the bottom of the tube. It is essential that the color should appear within 5 minutes, as some color is seen in normal urines after a longer time. [D.L.E.]

5.—Lipman-Wulf makes some rather desultory remarks concerning his work with methylene-blue as an index to the functional activity of the kidneys. He tested various animals with methylene-blue and found that the excretion began within 1/2 hour to 6 hours, and lasted from 24 to 52 hours, and in one case even 100 hours. There was no definite relation between the excretion of the dye itself and of the chromogen. With compensatory hypertrophy of one kidney it was evident that the excretion began very rapidly. In a woman, from whom one kidney had been removed, he found that the dye appeared in the urine during the first half hour, and the excretion lasted for 96 hours. As to the conditions in nephritis, Bard has stated that there are two varieties of disturbance. In one, with interstitial nephritis, the dye is slowly excreted, while in parenchymatous nephritis the dye passes abnormally readily. Lipman-Wulf made some experiments upon animals chiefly by the injection of cantharidin and other kidney poisons, and found that the dye was rather rapidly excreted, but that chromogen was still found in the urine as long as 70 hours after the injection, and in some cases the dye itself was not excreted as rapidly as is normal. These results did not, therefore, confirm the statements of Bard. It is quite possible that there are certain portions of the kidney parenchyma which have the specific function of excreting the coloring matter, and that, therefore, disease of these portions of the kidney will cause characteristic changes in the excretion. He attempted to determine some characteristic functions of various portions of the kidney by administering mixtures of dyes, and then observing the color seen in subsequent sections of the kidney, but had no satisfactory results. He thinks that this method may, however, lead to better results through its more extensive use. [D.L.E.]

6. Disinfection of the Hands. G. J. MÜLLER.

2.—The case which gave rise to the present report was that of a woman of 41, who had extrauterine pregnancy with rupture, free hemorrhage into the peritoneal cavity, collapse, and a rapid reduction of the hemoglobin to 25%. The urine for 2 days contained a marked amount of hemoglobin; 5 days afterward she had another severe attack of hemoglobinuria, which lasted for 4 days. The main point in the case

that after a large effusion of blood in the peritoneal cavity, 2 attacks of hemoglobinuria occurred. It was, therefore, a "posthemorrhagic hemoglobinuria." The possible explanations of its occurrence are mere absorption of the hemoglobin in unchanged form and its excretion as such, and, on the other hand, the production of a hemolysin through the absorption of the blood, this hemolysin causing actual solution of the patient's own blood-corpuscles and thus producing hemoglobinemia and hemoglobinuria. The first suggestion seems improbable. If it were correct one would expect hemoglobinuria frequently after hemorrhage, but it is extremely rare, indeed almost unobserved. The second possibility is accepted as being the most probable cause. The explanation given is this: Normally hemolysins are not active because they are combined with antihemolysins in the red blood-corpuscles or elsewhere. It is quite possible that if they became free in solution they would become active in any person. In the case reported there was a large abdominal effusion of blood which was very rapidly absorbed. It seemed probable, therefore, that much hemolysin was rapidly dissolved out, and that the organism was unable to provide quickly enough a sufficient amount of antihemolysin and some solution of the blood-corpuscles took place in this way. [D.L.E.]

3.—The case reported was that of a woman, 67 years old, who had pains about the thorax and disturbance of breathing, with increase of these disturbances, cough, loss of strength, and other indefinite symptoms, which were at first thought to be hysterical. Subsequently she came under Kalischer's observation, and it was found that she had marked tenderness over the ribs with some nodosities of the ribs, and that the urine contained considerable amounts of albumose (Bence Jones bodies). A diagnosis of myeloma of the ribs was therefore given, and a fatal prognosis established. The symptoms increased, and the patient died about a year and a half after the beginning of her pain. The postmortem examination showed that the ribs were filled with a substance which looked much like a semifluid splenic pulp, the spongy and compact bony substance had almost completely vanished, the bony tissue of the ribs consisting of a very thin shell, scarcely thicker than paper. The ribs were broken in several places, they showed numerous swellings, and could be readily broken to pieces. The humerus of one side was also examined, but showed scarcely any changes in the marrow. The case was, therefore, one of myeloma of the ribs. Microscopic examination showed that it was a hyperplasia of the marrow of lymphoid character. The marrow of the humerus showed practically normal conditions. The case ran a fairly typical course for this disease, and the urinary conditions were characteristic, consisting chiefly in precipitation upon gentle heating, solution of the precipitate upon more active heating, and a redeposit of the precipitate upon cooling. No Bence Jones bodies were found in the marrow or in the ribs or humerus. The amount of albumose in the urine was about 0.55%. According to the recent work of Magnus Levy this substance is midway between an albumose and an albumin. It is a striking fact that it has been observed only with great rarity in cases of pernicious anemia or leukemia with marked involvement of the bone marrow. In a case of leukemia and one of pernicious anemia which Kalischer observed recently, the Bence Jones substance was not present in the urine. It is also striking that myeloma may be present for a long time and may involve a large amount of bone marrow without causing any marked blood change. The nervous symptoms frequently seen in these cases may be due to the general reduction of health that comes with the condition, they may be due to actual pressure of growths, or they may be due to organic lesions of the nervous system. Sometimes there are paralytic symptoms which are explained by organic changes in the nervous system. [D.L.E.]

5.—The method recommended is based upon the fact that if one adds to a mixture of eosin and methylene-blue an alkali, the staining result will chiefly be due to methylene-blue, while with the addition of acid the eosin stain becomes more marked and may be made to become the controlling stain if enough acid is added. The mixture recommended is as follows: 0.5% eosin-solution in 70% alcohol, and an equal amount of concentrated watery solution of methylene-blue. This mixture ordinarily causes a deep blue stain. After this a dilute (1%) acetic acid is added, drop by drop, and the mixture tested; after each addition of acid it will be found

that the resulting stain shows more and more of the eosin element, until after the addition of about 10 to 15 drops of acid to 50 cc. of the stain the staining result finally becomes a satisfactory mixture of the eosin and methylene-blue, affects and does well for staining the nuclei, the granules of the leukocytes, and the protoplasm simultaneously. [D.L.E.]

1. The Relation Between the Nose and the Female Sexual Organs. ARTHUR SCHIFF.
2. A Case of Unilateral Hypertrophy of the Breast. BERNARD ENGLÄNDER.
3. Remarks upon Phosphorus in the Treatment of Rachitis. MONTI.

1.—Schiff first quotes from Fließ's work upon this subject, in which he calls **two areas upon the mucous membrane of the nostrils** (the anterior part of the lower turbinate, and the tuberculum septi), "genital spots," since they become hyperemic during menstruation. Besides, in cases of dysmenorrhea, he says that cocaine the lower turbinate causes the hypogastric pain, and cocaine the tuberculum causes the lumbar pain, to disappear. Further, should this be so, the dysmenorrhea can be permanently cured by cauterizing the "genital spots." Not only is this true in nervous dysmenorrhea, but in many of those cases associated with disease of the sexual organs, also. In pure mechanical dysmenorrhea, however, associated with stenosis of the cervix uteri, antelexion, etc., this is not the case. Schiff tested this in 47 cases, in 34 of which two drops of a 20% solution of cocaine upon these genital spots caused the pain of dysmenorrhea to disappear temporarily, not only once, but whenever applied. Nine of the 13 negative cases showed gynecological conditions. His tests numbered over 200. They were carefully made, suggestion being excluded. When water was used, and not cocaine, the pain persisted. By using other anesthetics (weaker cocaine solutions, suprarenal, etc.) he shows that this is due to anesthesia of the "genital spots." In 12 out of 17 cases of dysmenorrhea cauterizing the genital spots was followed by permanent recovery. Further experiments showed plainly the close connection between the hypogastric pain and the mucous membrane over the lower turbinated bone. [M.O.]

2.—Engländer reports a very rare case, a woman of 33, whose **right breast** was much hypertrophied. In her mother, also, the right breast was much larger than the left. During two pregnancies her breast grew much larger. Yet she had not enough milk for her second child. She refused operation, in spite of the huge size of her breast. A detailed review of the literature is given. [M.O.]

3.—After a detailed exposition of the subject, Monti says that **phosphorus** was first used for rachitis in 1838, and in 1863 Trousseau's prescription was widely circulated. Wegner's experiments do not show how rickets occurs, nor that it can be cured by phosphorus. Clinically, phosphorus has not prevented the progress of rachitis, nor has it caused the slightest improvement. Nor does phosphorus act any better with cod-liver oil, as it cannot be proved how much phosphorus exists in each dose, nor whether the phosphorus does not soon become phosphoric acid. Monti agrees with Zweifel that no specific action of unoxidized metallic phosphorus has been proved either experimentally or clinically. [M.O.]

18.—Blum has performed a series of experiments upon the thyroid gland, that appear to modify our views of the physiology of this organ considerably, and to indicate to some extent, new methods of research and treatment. A large number of dogs were sacrificed, so large a number in fact that Blum believes that accidental features are practically eliminated. It was found that of those animals that were fed, during the preliminary period and after the experiment, exclusively upon meat, 96% died, the great majority from tetany. The remaining 4% were immune to the results of thyreo priva, and also to all other forms of poison that are elaborated from the food. In the animals which were fed exclusively upon milk for a considerable period before the operation, and with the same substance after the operation, the mortality was only about 60%. A curious fact was, that if after they remained healthy upon the milk diet for a considerable time the animals were given meat, they exhibited all the symptoms of loss of thyroid. If the animals were kept upon a mixture of milk, bread and meat they remained perfectly well. Therefore the extractive materials in meat are certainly not concerned in the poison that is produced. Blum therefore believes that a poison is manufactured in the gastrointestinal tract from the essential constituents of the meat that is consumed. As a considerable proportion of animals died on milk diet it is reasonable to suppose that the same poison is produced from it that is produced from meat, but that in the majority of cases the quantity is considerably less. He calls this poison "enterotoxin." It is rather difficult to explain, however, why suckling puppies invariably died after the removal of the thyroid, although they were always nourished exclusively upon milk. All the animals that survived apparently did so largely as a result of the production in their blood serum of some antitoxic substance; for, if blood serum obtained from them is injected into animals manifesting a severe form of thyroid cachexia, it is often possible to preserve the latter for some time. The function of the thyroid gland appears from these studies to be the neutralization of toxic substances circulating in the body. From these it manufactures the thyreo toxalbumin, a substance that has a considerable affinity for iodine, although this element has nothing to do with the essential functions of the thyroid glands, as is proved by its total absence in the thyroid glands of very young animals. The thyreo toxalbumin is itself, under certain circumstances, toxic, although many animals either possess a natural immunity to it or are capable of acquiring it. Such animals, however, do not possess an immunity to enterotoxin alone. The symptoms of thyreo priva, therefore, are not due so much to an autointoxication as to an overwhelming of the system with the poisonous substances produced in the intestinal tract, and in cases of this condition, in order to diminish this poison as much as possible, a milk diet is apparently indicated. [J.S.]

19.—Cohn having had his suspicions aroused regarding the nature of the colostrum bodies in milk by the fact that they manifest ameboid movements when upon the warm stage, has endeavored to determine this point by microchemical reactions, that is to say, he stained them with Ehrlich's triacid stain, and determined that they possess neutrophilic granules. They differ from leukocytes chiefly in their size, and in the possession of numerous fat granules, however as the result of careful studies upon the milk of women in the process of weaning, he found that the fat granules were simply present in the protoplasm as the result of imbibition, and that when they disappeared the leukocytes resumed their normal appearance. The nuclei of the colostrum-cells resembled in all respects the nuclei of the polymorphonuclear leukocytes. It is difficult to explain why at

certain periods during lactation, particularly the very beginning, the colostrum cells should be present in such great excess. We can explain this either by supposing greater congestion at these periods, or the presence of the products of bacterial metamorphosis at the orifices of the glands, or the secretion of some chemotactic substance from the blood. Cohn believes that during gestation a certain amount of secretion collects in the glands, which, after parturition is stimulated by the greater activity of the bloodstream, and manifests then its chemotactic qualities. In some cases it has been observed that after the ninth day there may be an increased secretion of colostrum-cells. Tais, Cohn believes to be the result of a partial aplasia or insufficiency of the glandular tissue. It has been observed in support of this that the number of colostrum-cells diminished as the quantity of milk increased. In some cases there is unilateral secretion of colostrum cells, which can be explained by partial insufficiency of the glandular tissue on that side. Cohn also discusses some very interesting features of lactation, which however, cannot properly be considered in an abstract. [J.S.]

20.—Herxheimer has made a series of studies upon the fibrinous inflammations of the pleura and intestine. The method employed was staining by various methods, but chiefly Weigert's fibrin method, of pleura contents, postmortem material in Göttingen. The object was to determine the part which the endothelial cells take in the inflammatory process. By staining the elastica he was able to determine that they lay beneath the fibrinous layer, and formed a continuous layer, covering also the portions upon which no fibrinous exudate existed. Under exceptional circumstances a few cells were found on the outside of the exudate, or mixed with the fibrin. This may be regarded as accidental. Many of these endothelial-cells were swollen and showed distinct signs of proliferation similar to the changes described as the result of irritation by foreign bodies. Above the cells, clefts were not infrequently found, but these did not represent lymph spaces because they were not lined by endothelium. The signs of proliferation consisted in swelling of the cells, formation of giant cells, karyokinesis, and the arrangement of the cells in several superposed layers. In no instance did they show any signs of conversion into connective tissues. The explanation for the proliferation was, the formation of clefts that needed covering, the replacement of discarded cells, or the action of an irritant. Investigations upon the intestine were made chiefly for the purpose of determining the presence of true fibrin. This was found in a variety of cases, and always most pronounced in the submucosa. In one case, however, diagnosed as a pseudo-membranous enteritis following pyemia, no fibrin was found and the membrane present determined to be due to the numerous emboli of micrococci. Nevertheless, Herxheimer concludes that fibrin formation is an important element in intestinal disease. [J.S.]

21.—Von Stein has carried out an interesting series of experiments with the object of determining what effect various chemical solutions have upon the formation of crystals from hemoglobin. The method was as follows: Blood was obtained from guinea-pigs, rapidly defibrinated, and a drop placed upon a slide and then, by a rather delicate manipulation, covered with a film of Canada balsam. At the end of 24 hours it was examined, and the crystallization was usually complete. Various saline solutions were added to the drop before covering, and their influence upon crystallization observed. Distilled water in small proportions made the crystals smaller and paler, and when 2 to 3 drops of water were added to the blood they failed to form. Solutions of sodium chlorid caused at first blunting of the edges of the crystals, smaller crystals, and finally complete disappearance of them. Similar results were obtained from potassium chloride, sodium sulphate, potassium chlorate, ammonium sulphate. Hydrogen sulphide prevented the formation of crystals; carbon monoxide gave rise to the formation of blunt tetrahedrons of blood red color; nitrous oxide did not interfere with the formation of the crystals, and anhydrous sulphurous acid prevented it entirely.

22.—Blauel reports 2 cases of sarcoma of the intestine. The first, a man of 33, at the age of 26 commenced to have gastric disturbances which lasted 3 or 4 years. At the age of 31 he had a severe inflammation of the appendix. Four or 5 weeks later he noticed a tumor the size of a pigeon's egg in the right iliac region. This gradually in-

creased in size. Later it reached the size of a child's head. The patient had an eruption of blisters all over the body, that suppurated. The tumor from this time increased rapidly in size, and soon occupied the larger portion of the abdominal cavity. It became infected with the colon bacillus; was incised, and a large portion of necrotic tissue removed. The patient died from exhaustion. At the autopsy the abdominal organs were found much displaced, and the tumor, which was larger than an ordinary man's head, involved the cecum and the commencing portion of the ascending colon, the walls of which formed a rigid tube. Microscopically it was a small round cell sarcoma. The second patient, a woman of 66, had suffered for about 6 months with pain in the right side of the abdomen. At an operation a tumor was found in the ileocecal region that had formed dense adhesions with the right adnexa. The patient died of thrombosis and decubitus. At the autopsy a small round-cell sarcoma of the cecum and ileocecal valve was found. Blauel calls attention to the extreme rarity of sarcoma in this region. They are all apparently of the same historical construction, and in the majority of cases arise from the serous coat; as a result, a common symptom is the absence of the ordinary signs of intestinal obstruction. [J.S.]

23.—Walbaum has undertaken a series of investigations upon 45 cases of **purulent peritonitis**, in order to determine how much of the actual wall of the intestine was affected by the inflammatory process, and what changes occurred in the ganglion cells of the intestinal plexus. He found in nearly all cases that the muscular coat escapes, but that there is an infiltration around the bloodvessel walls, and round cells in any cases extend into the submucous tissues. The bloodvessels passing through the muscular coat also showed perivascular infiltration. The cellular proliferation affects chiefly the connective tissue cells. There is often fibrinous exudate in the intestinal wall. The ganglion cells of the intestinal plexus were fixed with a 2% formalin solution, and then stained, either with osmic acid or with osmic acid and hemotoxin. Even in normal cells a few fine fat drops could be found; but in the pathological cells these were often considerably increased. The absence of the nucleus is not necessarily a pathological sign. Many of the cells were vacuolated or showed hydropic degeneration. Chromatolysis of the nucleus was not infrequent. He concludes therefore, that the inflammatory process extends into the intestinal wall and causes alteration in the protoplasm and nuclei of the ganglion cells. [J.S.]

24.—(See editorial.)

25.—Rosin and von Fenyvessy have already shown by means of osmic acid, that **granular pigment in the ganglion cells of the nerve system** is probably fat. The discovery of the micro-chemical reaction with sudan III, however, have impelled them to undertake a new series of investigations in order to determine as positively as possible, that their previous statement was correct. The sections were placed in formalin, cut on the freezing microtome and placed for 24 hours in a saturated solution of sudan III in 80% alcohol, and then mounted in glycerin. The granular pigment stained an intense scarlet. Certain peculiar bodies in the adventitia of the bloodvessels also stained a deep scarlet, and the myelin sheaths a pale red. In the sections treated with absolute alcohol and ether the pigment completely disappeared, proving its true fatty nature.

26.—1. Krause having written to Virchow inquiring whether he agreed with the principle set forth by Gegenbaur, that the various tissues arise from individual embryonal layers, and that the endothelium represent layers of connective tissue cells, received from Virchow an answer in which he insists upon the doctrine of metaplasia, and states that in endothelioma, cells with epithelial characteristics may occur. 2. Brion reports an interesting case of extensive **atheroma occurring in a girl 15 years of age**, who had had successive attacks of articular rheumatism for 10 years. The mitral valve was stenosed, the aortic valve insufficient, and in the posterior mitral leaflets there was a cavity containing an emulsion of fat with some calcium crystals, and a few compound granular cells. It represented therefore, an atheromatous degeneration. The color of the fluid was white instead of yellow. The interesting features are that the atheromatous process occurred in the interior of the valve, and in a girl of 15 years. 3. Hansemann defends his hypothesis of **anaplasia** against the criticisms of Beneke. He

maintains that although it is only an hypothesis, it explains a great many facts that, in the present state of our knowledge, cannot be better elucidated. [J.S.]

Revue de Médecine.

January 10, 1901. [21me Année, No. 2.]

7. Purulent Hygroma Due to Gonococcus Infection. V. GRIFFON and L. NATTAN-LARRIER.

1.—E. Gaucher has shown in previous papers that all the toxic forms of **nephritis**, toxic infectious and autotoxic, while primitively epithelial often become of the chronic intestinal form. This author, in conjunction with E. Sergent, now undertakes to prove that gravid nephritis becomes also chronic intestinal nephritis presenting especially the *bruit de galop*, and the identical anatomical lesions. Gravid nephritis becomes identical to those forms of nephritis caused by slow and prolonged intoxication and should be classed with them. A few carefully studied cases are cited. [T.L.C.]

2.—Lagrange points out the necessity of carefully studying each particular case of **cardiac trouble** and regulating any systematic exercise upon the principle that the cardiac action is the resultant not of a single but of many forces, all of which must be taken into account. The article (not complete in this number) discusses with judgment the possibilities of helping certain cardiac cases and explains the rationale of the method. The effect of massage upon engorged veins is familiar to all and the effect also, upon the arterial system in the free circulation through the sluggish part, which must beneficially influence cardiac action. In cases of complete paralysis of one side, for instance, the systematic exercise of the well side will greatly assist in adjusting the circulation to the changed conditions. The influence of groups of muscles and their antagonists and the possibility of favorably changing the arterial tension are discussed. The value of deep, regular breathing upon the circulation is not underestimated, and the keynote of moderation in all systematic exercises to bring about a favorable result with the least effort is insisted upon. [T.L.C.]

3.—Spillmann reports 2 cases of **primary, progressive myopathy** in girl children of 9 and 7 years of age respectively. The cases present some interesting features. In the second case the atrophy began in the muscles of the calves, then invaded the thighs, lumbar region and trunk. In this case the atrophy was arrested at this level, but in Case 1 the muscles of the upper extremities were also affected, the face alone being exempt. These 2 cases resemble the type described by Leyden, Möbius, and Eichhorst. There seemed to be no hereditary tendency in these cases. In testing the electric contractility of the muscles, the excitability to the galvanic current was found diminished in both cases, but in the first case there was an abolition of faradic excitability in the extensors of both arms. This absence of faradic excitability of muscles which is present generally in lesions of the peripheral nervous system shows how great the difficulty is of separating these myopathies from amyotrophic conditions due to lesions in the medulla. [T.L.C.]

4.—Oddo in a paper (incomplete in the present number) has made an elaborate study of the **localization of the symptoms in Sydenham's chorea**. He summarizes the opinions as to the localization of the choreic movements. The movements are rarely general at the onset. They begin in the upper extremity, or the face; or rarely, in the lower extremity. They spread over the corresponding half of the body and finally attack the opposite side. Pure hemichorea is very rare. In Oddo's study of 144 cases, the onset was

general in 25 cases only. It was hemilateral in 111 cases of his series. Considering the disease at its height, Oddo found hemichorea in 24 cases; general symptoms with predominance of hemilateral symptoms were seen in 91 cases; symmetric general involvement was present in 29 cases. [T.L.C.]

5.—In a valuable contribution to the study of the **tendon reflexes in typhoid fever** Remlinger has found that in 32 cases out of 100 they are exaggerated; in 22 out of 100 they undergo no change; they are diminished in 17 cases out of 100, and abolished in 29 out of 100. There does not seem to be any constant relation between the type of the fever and the state of the reflexes. At times it appeared that exaggeration was present in grave cases, especially the **ataxic** and **ataxo-dynamic** forms. The preservation of the normal reflexes was noted especially in the benign cases and these with pronounced gastric symptoms. During the course of convalescence a marked tendency to exaggeration of the reflexes was observed. The epileptoid trembling of the feet was found in 20 cases out of 100, but it was less frequent than the exaggeration of the patellar reflex. It is often unilateral and often coincides with exaggerated tendon reflexes but it was observed at times in cases of normal, diminished or even absent reflexes. This tremulousness was observed especially after repeated percussion of the patellar tendon. He points out that this condition does not seem to manifest itself at the drop of the temperature, but often coincides with profuse sweats and polyuria and appears to deserve notice as a true critical phenomenon. The percussion of the tendon of Achilles sometimes provokes in typhoid fever an epileptoid trembling of the foot, which the author terms **Achilleian** to distinguish it from the ankle-clonus proper. He found at times a dissociation between the patellar reflex and the trepidation elicited from the tendon of Achilles. The epileptoid trembling of the knee is not rare in typhoid fever. It is found to be bilateral and always accompanies an increased knee-jerk. The author observed no single case of dissociation. The contralateral patellar-reflex (crossed reflex), the vertical shaking of the foot and toes elicited by percussion of the patellar tendon, is one of the rare, but extremely interesting, phenomena of typhoid fever. This movement is most marked in the limb percussed, but a decided movement of extension is also seen in the opposite leg. The cutaneous reflexes of typhoid fever present no particularly interesting changes. Only the plantar cutaneous reflex has been studied. The dissociation between the exaggeration of the tendon reflexes and the epileptoid trembling does not appear to be explicable upon the ground of the localization of the hyper-excitability of the medullary center of ankle-clonus; by the physiological abolition of the tendon reflexes; or, finally, by the cortical origin of the epileptoid trembling and the medullary origin of patellar reflex. That the tendon reflexes are true reflexes, the contralateral patellar reflex proves conclusively. Explanation of the epileptoid trembling is simple, if we regard them as simple idiomuscular contractions. [T.L.C.]

6.—Vergely reports the case of a woman, aged 68 years, of good family history, who sustained a fall upon the chest and abdomen. The injury was slight and no traces were present on examination. Some 3 years before the accident she had lost her husband and the shock had proven a great one to her nervous system. Some hours after the fall the symptoms of **angina pectoris** set in. This condition was relieved and was soon followed by polyuria and great thirst. Passive congestion of the lungs also developed. Sugar was present in considerable quantity and the nervous symptoms increased in severity. There were no indications of glycosuria before the accident, although the urine was not examined. The heart, upon examination, presented no gross lesions, but the arteries were somewhat sclerosed. Vergely gives an excellent resumé of the literature of traumatic diabetes and gives copious bibliography. Vergely concludes indirect traumatism often induces diabetes in predisposed persons. The onset of unusual nervous symptoms following trauma of this nature should lead us to expect traumatic diabetes and the urine should be examined carefully. Anginoid attacks are common in diabetes and also demand careful investigation as to the possibility of the presence of this disease. [T.L.C.]

7.—Griffon and Nattan-Larrier report from Dieulafoy's clinic a rare case of **hygroma**, purulent in nature, in which the presence of **gonococci** was established definitely. The

patient, a woman of 40 years, entered the hospital with agonizing pain in the lower extremities; a tumefaction was present in the region of left hip. It was found by careful, repeated examinations that the swelling was located between the fascia lata and the great trochanter. Fluctuation was soon observed and exploratory puncture performed. The material withdrawn was thick and purulent, and examination by cultivation revealed the presence of the gonococcus in pure culture. [T.L.C.]

La Semaine Médicale.

January 9, 1901.

1. General Review: The Action of Yeasts Introduced into the Digestive Tract. P. NOTÉCOURT.
2. Practical Surgery: Technic of the Operation of Empyema. MAURICE CAZIN.

1.—Attention has lately been recalled to former observations dealing with the **action of yeasts** introduced into the **digestive tract**. The view is held by many that the yeasts possess favorable action upon certain conditions and serve as valuable therapeutic agents. Notécourt has reviewed the experimental work done upon the subject. Many difficulties arise in the prosecution of the investigations, but there is a certain unanimity of opinion upon many points. It has been determined that the best range of temperature for their development is between 30° C. and 35° C., but fermentation is still possible at 45° C., so that the body-temperature is satisfactory for their action. The saliva is found to have no unfavorable influence. However, the action of the gastric juice presents a double problem. It must be determined whether the gastric juice destroys the yeasts and secondly whether they are able to produce fermentation in the presence of the gastric juice. The alkalinity of the stomach contents after a meal is no bar to the action of fermentation which we know can proceed in an alkaline medium. It has been determined that the gastric juice has an unfavorable action upon the yeasts, but not to the point of preventing the passage of a certain proportion of the yeasts, still active, into the intestine. When the yeasts reach the intestines we have to consider besides the alkalinity above referred to, the action of the bile, pancreatic secretion, and the microorganisms present in the contents. It has been proven that the presence of the bile greatly retards the action of many forms of yeasts; the action of the intestinal juices and pancreatic juice is not as certain. Effects of microorganism have not been systematically studied, but it has been found generally that the vitality of yeasts is not sensibly affected by their presence. The yeasts are able to supply the necessary oxygen for their existence by deriving it from the sugars. It is to be remembered that oxygen may be found free in the stomach. It is found necessary, in order to provide the most advantageous medium for the development of yeasts in the digestive tract, to give a liberal supply of sugar with the yeasts. After ingestion of yeasts it is found that the motor activity of the stomach is decreased, that the production of hydrochloric acid is retarded, but that pepsin is present in sufficient quantities. The effect of yeast upon the intestinal contents with special reference to the utilization of sugar is of importance in diabetes for the reason that in the presence of the yeasts, a patient may partake of liberal hydrocarbon diet without increase of the glycosuria. Certain yeasts are found to act unfavorably upon certain microorganisms (in experiments performed *in vitro*), to have no effect upon others, and to even increase the activity of the microorganisms in a few, as, for instance, the bacillus pyocyaneus. Notécourt and others claim a decided lessening of certain **toxins**, especially of **diphtheria**, when yeasts have been given. Large quantities of yeast (witnessed in beer poisoning) produce diarrhea, vomiting, fever, and coma. This is probably due to the evolution of carbonic acid gas and the poisonous effects of this gas. In animals abdominal distention and asphyxia are observed. Among the diseases attributed to the effects of alcoholic fermentation are dilatation of the stomach, acute gastrointestinal catarrh, chronic gastritis and anthrax. Yeasts have been used therapeutically in furunculosis, with or without diabetes, in enteroptosis, in gastrointestinal disorders of infants and in the infectious fevers. The results have been unsatisfactory in

many cases. The necessity arises for experimentation as to which varieties of yeasts are to be employed and the precise rationale of the action. [T.L.C.]

2.—Maurice Cazin contributes a paper upon the technic of the operation of empyema. He advocates the use of local anesthesia and employs a 2% solution of cocaine in a syringe of 2 grams capacity. Perfect local anesthesia is obtained in fifteen minutes. In limited encysted effusions the area of dullness itself will give us the point of election for operation. In general effusion the polleurotomy should be performed at the posterior axillary line at the ninth interspace. The technic of the operation follows. The writer points out the importance of free drainage and recommends flushing the pleural cavity, with aseptic or mild antiseptic solutions, except in the case of gangrene of the pleura. [T.L.C.]

January 16, 1901.

1. Potain,—Obituary Tribute. P. TEISSIER.
2. On the Semeiological Value of the Variations in Timbre and Intensity of Abnormal Heart-Sounds, and the Influence of the Ventricular Elasticity on the Closure of the Mitral Orifice. POTAIN.

2.—Potain in one of the last works of his pen, discusses the semeiological value of the variations of timbre and intensity of abnormal cardiac bruits, with especial reference to the part played by the ventricular elasticity and the closure of the mitral orifice. He briefly narrates the well-established fact that valvular lesions give rise to bruits which serve us as guides of the precise valvular defects present, and mentions the part played in the modification of these murmurs by the varied states of the superimposed lung. The valvular closure is produced by the systole of the ventricles, directly for the auriculoventricular valves and indirectly for the sigmoidal, and the fall and shock of the sigmoidal is caused by the arterial pressure which acts upon their superior surfaces, and this arterial pressure being the work of the ventricular systole it is always this systole which brings about the closure of the orifices and the valvular sounds, and by the intensity of this ventricular systole is determined the intensity of the bruit. Potain calls attention to the accessory causes not generally taken into account which may modify the bruits. The first mitral sound especially is modified by the cushion of blood as well as by the superimposed lung interposed between the heart and the chest-wall. It is generally laid down that hypertrophied states of the ventricular wall attenuate the sounds, while simple dilation augments them. Potain, however, shows that there are manifold variations of this rule; for the augmentations or diminutions are often transitory and cannot be attributed to constant organic changes. Again, the blood-wave in the vessels is often strong, while the valvular sounds appear weak and this is a curious alteration which the state of the ventricle will not explain. Potain seeks the cause in the modification of the mechanism of valvular closure. He holds that the closure of the mitral valves is determined by the elasticity of the ventricle, which fact accounts for the variation in intensity of the first sound, and he further suggests that an analogous explanation may be given for alterations of the second sound. [T.L.C.]

January 23, 1901.

1. Thoracic Pain in Peritonitis Following Perforation of the Stomach. M. J. L. FAURE.

1.—Faure has observed the symptom of thoracic pain in the peritonitis followed by perforation of the stomach. In his first case the pain was at first of sharp, violent character, and confined to the stomach, then radiating to a point below the left shoulder. The patient presented signs of abdominal distention with general abdominal tenderness, but no appreciable point of maximum intensity. Laparotomy was performed, and the lesser cavity filled with pus, which appeared to come from the region of the appendix. Free drainage was established, and the patient died 5 hours after operation. At postmortem a perforation of the stomach was found. In his second case, sharp pain from a similar condition was felt between the shoulders. Autopsy following the operation which showed the presence of a general peritonitis, confirmed the diagnosis of perforation from gastric ulcer. Faure

concludes that acute morbid conditions of the abdominal viscera and, in particular, perforation of the stomach are often accompanied by thoracic pain, either dorsal, scapular, or intrascapular. In cases of general peritonitis of undetermined origin, the recognition of this symptom is of the greatest importance. We should make the most careful inquiries as to the existence of this pain at any time during the disease. Such knowledge would indicate the point of election for the surgical incision. [T.L.C.]

Révue de Chirurgie.

January, 1901. [21me Année, No. 1.]

1. Ligation of the Abdominal Aorta. P. TILLAUX and P. RICHE.
2. The Treatment of Infected Wounds. OSCAR BLOCH.
3. The Study of Osteomalacia. G. GAYET and L. M. BONNET.
4. Phlebitis of the Left Leg with Appendicitis. EUGENE VILLARD and PAUL VIGNARD.
5. Ectokelostomy. VITRAC.
6. Some Remarks Upon a Case of Obturator Hernia. PIERRE FREDET.

2.—Only since Lister, have infected wounds been well treated. Naturally in every case the best result would be union by first intention, though union by second intention is often the best result obtained. All wounds contain microbes, yet infected wounds often heal by first intention. To prevent the growth of microbes in retained secretions, **antisepsis and drainage** are necessary. Bloch recommends the use of carbolic acid as an antiseptic. Dressings applied should always be **sterile**, and **drainage** should always be **adequate**. After being dressed, wounds must be kept immobile. The only general treatment advised is the use of the salicylates, with stimulants when necessary. The use of Marmorek's antistreptococcic serum, while probably innocuous, has not yet been proved so. Therefore Bloch does not advocate its use. [M.O.]

4.—After mentioning the occurrence of pleurisy, hepatitis, and psoriasis with **appendicitis**, Villard and Vignard have recently observed two cases complicated with **phlebitis of the left leg**. The first case occurred in a man aged 26 years. Three months before he had had his first attack of appendicitis. The second attack lasted 5 days, after which he was operated, the appendix, which was very long, being removed. On the day following the operation he complained of pain in the left leg. The next day dyspnea and fever began, followed, a day later, by the appearance of a marked phlebitis. Cough with bloody expectoration followed. Soon all the signs of a pulmonary infarct were found. The second case was very grave, with purulent appendicitis and phlebitis of the left leg following operation. Two other cases are also reported. Of these four cases 2 died. There would be nothing extraordinary in thrombosis of the right femoral vein. But it occurs more frequently on the left side, which is explained as a distant manifestation of the general infection, appendicitis. It is evidently metastasis through the circulation. Its occurrence as a complication in appendicitis makes the prognosis unfavorable. Its treatment is the same as for ordinary phlebitis. [M.O.]

5.—Ectokelostomy is an operation by which the sac of a hernia is kept open with drainage, the whole being displaced through a counter-opening in the abdominal wall, the hernia being then cured radically. Vitrac has performed ectokelostomy twice in women aged 54 and 84 years. Both had **strangulated femoral hernia**, and both recovered with excellent results. Cocain was used for one, the other, however, was done without any anesthetic. Vitrac describes the technic of the operation, dividing it into 6 steps; opening the hernial sac, and freeing it from all adhesions; making an incision into the abdominal wall, through which the hernial sac, after being freed from the anterior abdominal wall, is drawn; placing a drainage tube in the sac, protruding through the abdominal wound; performing the operation for the radical cure; and finally removing the drainage tube. By this method, all exudate in the peritoneal cavity is well drained off, and at the same time the drainage does not interfere with the radical cure of the hernia. Eight illustrations explain the technic of the operation. [M.O.]

6.—This **obturator hernia** was not discovered until

after death, upon the cadaver. No clinical history is known. After a detailed description of this hernia, Fredet concludes that obturator hernia may have a double sac. If this is the case, they are produced inside of the umbilical artery. The outer sac is supplied by the prevesical fascia. This explains the anatomic connection between the bladder and the hernia. The possibility of the production of the hernia inside the umbilical artery presupposes the presence of an artery, sometimes permeable, above and outside the neck of the hernia. The hernial sac, when in the subpubic canal, may cause painful, paralytic phenomena in the sphere of the obturator nerve; which phenomena decrease when the hernia emerges from the subpubic canal; yet the external obturator nerve may stop the hernia, so that it move behind the external obturator muscle. [M.O.]

Archives de Médecine des Enfants.

January, 1901. [Vol. iv, No. 1.]

1. Lithemia in Children. JULES COMBY.
2. Leukocytosis in Pneumonia and in Diphtheria. P. HEIM.
3. Empyema in Children. BÉZY and BAUBY.

1.—The symptoms of lithemia in children are so varied that they are not diagnosed positively without study, especially with reference to ancestry. For the children of gouty parents have a decided tendency toward the lithemic diathesis. After quoting cases reported by Ratchford and Whitney, Comby details 15 case-histories showing the many different symptoms found in lithemic children. He then classifies the symptoms under 7 headings, considering the most important **periodic headache**, and **cyclic vomiting**. The symptoms suggest a grave auto-intoxication, but the history of gout in the parents soon leads to the diagnosis of lithemia. The urine shows high specific gravity, with an excess of urea and uric acid. Hygiene, exercise, regular meals with little meat, and alkaline waters constitute the main treatment. [M.O.]

2.—The leukocytosis in croupous pneumonia and diphtheria in children depends upon the virulence of the microbes and their toxins, and the reaction of the organism to them. From 19 cases of croupous pneumonia, in which Heim counted the leukocytes, the result was a constant increase of the leukocytes up to one or two days before the crisis, when they fell suddenly again to normal. When lysis occurred rarely, the leukocytes decreased gradually also. Hypoleukocytosis is always a serious prognostic sign, though not necessarily fatal. All the cases showed a great increase in the neutrophilic polynuclears, with a relative decrease in the lymphocytes. **Eosinophiles are absent in croupous pneumonia**, only appearing a day before the crisis. This will help to differentiate croupous pneumonia, meningitis, pleurisy, and tubercular pneumonia, in which diseases the eosinophiles are abundant. In diphtheria the leukocytosis may be extreme, Heim having seen 28,080 in one case. The leukocytes increase very rapidly, even before the membrane appears. Then they decrease gradually. If complications exist, the leukocytosis persists. Injections of antidiatheritic serum decrease it, but it rises again later. If the leukocytes do not decrease in number after a serum injection, enough serum has not been given. The polynuclear leukocytes are increased, with a proportionate decrease in the lymphocytes. Eosinophiles are very few in pure diphtheria, but are seen if the throat condition is due to streptococcus. If the polynuclear neutrophils remain above 50% the day after the serum injection, the prognosis is grave. [M.O.]

3.—Bézy and Bauby report 3 cases of empyema in children. The first case occurred in a boy of 4, who had a sudden attack of dyspnea, following a few weeks after pneumonia. As there was distinct movable dullness on the left side, he was tapped, two liters of pus, which showed pneumococci, being removed. A week later he was again tapped and a liter of pus removed. Operation followed, with drainage, and he recovered in another week. The second case, a boy of 9, had empyema on the left side following typhoid fever. He was tapped and operated on at once. The yellow pus contained streptococci and colon bacilli. He also recovered. The third case, a boy of 30 months, had had diarrhea for over two months when dullness was noted upon the apex of the right lung. When ready to tap him, he vomited a

cupful of pus which contained streptococci, staphylococci, and colon bacilli. He continued to expectorate pus, but recovered gradually in two months more. These histories are discussed in full. [M.O.]

Journal de Médecine de Bordeaux.

February 3, 1901. [31me Année, No. 5.]

1. A Case of Penetrating Gunshot Wound of the Abdomen. M. HASSLER.
2. Subdural Serous Cysts Following Cranial Injury. F. VILLAR.
3. Mercurial Injections in Syphilis. A. GUÉRIN.

1.—The patient, a native bugler of the Fourreau-Lamy expedition in Africa, received his first wound in the right leg, and his second, upon the same day, in the abdomen. The wound was dressed at once, and he was taken to camp in a canoe. He was kept at rest for 23 days. Then, as camp was moved, he started, mounted upon an ox, which method of locomotion caused him so much pain that he got down and walked, supporting himself upon his gun. **Six weeks later he reached Bordeaux.** A probe was introduced into the fistula, which had existed since he had been shot, and the bullet was found. No skiagraphs were made. He was thin and anemic; otherwise, however, in good condition. The bullet, weighing 20 grams, was extracted with difficulty. The intestines were not opened, the entire fistulous tract being dissected out. He recovered in 6 weeks and left for his African home. This case was of great interest, because the bullet had a steel casing; because its deformity showed that it had already struck once and had then been deflected; and because calcareous particles and bits of clothing were found in the abdominal fistula. [M.O.]

3.—Guérin describes the different preparations of mercury which can be given hypodermically. He also details the doses and the technic of the injections. The soluble salts of mercury, the biniodid, benzoate, and bichlorid can be given in fractional doses, or calomel may be employed, though it may cause intense reaction at the seat of injection. **Guérin advises the administration of mercury in subcutaneous injections as a routine practice.** [M.O.]

February 10, 1901. [31me Année, No. 6.]

1. Unrecognized Cases of Whooping-cough. R. SAINT PHILIPPE.
2. Subdural Serous Cysts Following Cranial Injuries. F. VILLAR.
3. The Leukocytes in Cases of Cancer. AUCHÉ and VAILLANT.
4. A Foreign Body in the Rectum. A. FRAIKIN.

1.—Saint-Philippe says that pertussis may exist without the spasmodic cough, or the typical whoop. Sneezing may take its place, often. Râles are generally heard, and nasopharyngeal catarrh may be present, with adenoids. On account of its extreme contagion, and its ubiquity, he advises that every child with a longstanding cough be carefully watched. Children who expectorate are generally far advanced in whooping-cough. If pertussis be present, scratching the trachea will elicit a typical paroxysm. For the treatment, and to prevent the severe sequela, especially, minute scrutiny of all suspicious cases must be routinely practised. [M.O.]

2.—Villar details 2 cases of traumatic epilepsy, the attacks having occurred for the first time 14 and 4 years after the cranial injury. In both cases subdural serous cysts were found. They were caused by the traumatism, years before, which had set up hemorrhagic meningitis, the results of which these circumscribed serous cysts at the point of hemorrhage. The only treatment is trephining, with the evacuation of the cysts. In neither case was there a return of symptoms after operation. [M.O.]

3.—Leukocytosis is an acknowledged fact in cancer. Four cases are reported, the first, epithelioma of the tongue, gave 19,964 leukocytes; the second, scirrhus cancer of the stomach, showed 16,740 leukocytes; the third, rodent ulcer of the face of 7 years' duration, 5,890 leukocytes; and the fourth, a tumor of the abdomen, of unknown character, showed 21,700 leukocytes. The blood-examination in the third case, the rodent ulcer, showed the blood to be normal

in all respects. In the first 2 cases, the leukocytes were markedly increased in number, with a relative increase in the polynuclear leukocytes, and the lymphocytes. The count of the leukocytes in the last case suggests that the tumor may be cancerous, from the evident leukocytosis. [M.O.]

4.—Fraikin reports the case of a farmer, from whose rectum he extracted a brush-handle, without causing him any pain at all. After dilating the sphincter, with the patient in the knee-chest position, he caught one end of the wooden handle with difficulty, and slowly withdrew it. The farmer said that it had entered when he fell upon it from a ladder. He had had no symptoms, but the foreign body was easily felt through the skin. [M.O.]

Journal des Praticiens.

February 2, 1901. [15me Année, No. 5.]

1. Intravenous Injections of Normal Salt-Solution in Puerperal Hemorrhage. CHARLES MAYGRIER.
2. Post-Influenza Polyneuritis. BRETON.

1.—Maygrier gives detailed histories of 15 cases of hemorrhage treated by normal salt-solution injected intravenously, 7 of whom recovered. The other 8 died. In 7 cases, hemorrhage was due to vicious insertion of the placenta, to abortion, and to premature detachment of the placenta, each, in 2 cases; and it occurred with child-birth in 4 cases. The amount injected varied from 700 to 2000 grams. In many cases, subcutaneous injections were given besides. The indication for the injection is the severe anemia, the lowered general condition. Maygrier advises intravenous injections when subcutaneous injections have on effect, or when death seems imminent. They should even be repeated if necessary. [M.O.]

2.—Breton reports a case of polyneuritis in a chambermaid, aged 27 years, who was always nervous and excitable. She had had a distinct attack of hysteria some years previous. The polyneuritis appeared 3 months after an attack of influenza, and lasted 2 months. During the influenza, paralysis of the legs existed, but then disappeared. The neuritis affected both arms and legs. The left side was most involved. But the sphincters were at no time affected, and the muscular atrophy was slight. [M.O.]

Il Policlinico.

(Sezione Pratica.)

November 24, 1900. [Anno vii, Fasc. 4.]

1. Transactions of Congresses.
2. Contribution to the Study of the Rhythmical Shocks Imparted to the Head in Patients Suffering from Aneurysm. G. COCORULLO.
3. Contribution to the Diagnosis of Measles. G. MORANO.

1.—D'Urso (Italian Surgical Association, Rome, October, 1900) gave an account of experimental researches on the pathogenesis of hydronephrosis carried out on rabbits and dogs by ligature of the ureter. Rosa showed a case in which he had sutured with complete success a brachial artery wounded longitudinally during venesection by a phlebotomist. Bagi reported on 6 cases of tubercular peritonitis cured by the iodo-iodurate injections of Durante. Each injection contained from 1 to 2 cgr. of iodine, and from 22 to 90 injections were required to complete the cure in the different cases. Jaja described 4 cases of vesical exstrophy and 1 of epispadias treated by grafting the ureters into the rectum. The anal sphincters retained the urine well for 4 to 5 hours at a stretch. It was not found possible, however, to avoid ascending renal infection. Betagh presented 2 cases of papilloma of the urinary bladder diagnosed by aspiration of the vesical contents through a metal catheter. Diagnosis by the cystoscope was impossible owing to the turbidity of the urine from blood. Rizzo, arguing from the results of experiments on dogs, recommended the ligature of the spermatic vessels in cases of enlarged prostate, in place of division of the vas deferens. Pascale, from anatomical observations and experiments, drew the conclusion that in cases of hysterectomy for fibromyomata of the uterus, the ovaries, having already lost their function, may be removed in most cases without doing harm. In young women, however, he would leave them. At the Obstetrical and Gynecological Congress

(Naples, October 20-23) Pestalozza related 2 cases in which there was a recurrence of extrauterine pregnancy in the same patient, in 1 case for a second time. This recurrence is comparatively frequent in such cases, 108 of which he had collected from the literature of the subject. Clivio and Ferrari spoke on the subject of hematocele. [G.S.B.]

2.—Cocorullo describes a case of subclavian aneurysm exhibiting this phenomenon. The patient, a man 36 years of age, showed signs and symptoms pointing as was thought to aneurysm of the innominate artery, namely, asynchronism of the two radial pulses, an area of dulness higher up and more to the right than that usually associated with aneurysm of the aortic arch, and a double rhythmical movement of the head, vertical and rotatory. The autopsy revealed a dissecting aneurysm of the right subclavian and first part of the axillary arteries, proving that such rhythmical movements of the head are not peculiar, as is generally supposed, to aneurysms of the arch of the aorta. As to the cause of the movements, this varies according to the situation of the pulsating sac. In aneurysm of the arch they are due in part to the downward push given to the right bronchus and the backward push to the trachea (nodding movement); in that of the large intrathoracic vessels they result from the jar to the costal attachments of the scalene muscles and the clavicular attachment of the sterno cleido-mastoid (lateral rotatory movement). [G.S.B.]

3.—A short account of a series of cases of measles in which Koplik's sign was looked for. Of 15 infected persons, 10 (66%) showed the characteristic marks on the mucous membrane of the cheeks, from 2 to 4 days before the appearance of the general eruption. [G.S.B.]

December 1, 1900. [Anno vii, Fasc. 5.]

1. Why Was There an Increased Mortality from Diphtheria Among Children in Rome During the Present Year? L. M. SPOLVERINI.
2. On the Discovery of the Method of Rendering Animal Vaccine Bacteriologically Pure. T. R. DORIA.

1.—A study of the period extending from July 1, 1895, to May 31, 1900, shows that the introduction of the serum treatment of diphtheria into Rome reduced the case mortality of that disease from 60 or 70% to about 16%. At this latter figure the death-rate remained almost stationary during the first four years under consideration, when suddenly a sharp rise took place not only in the death-rate, which increased to over 28%, but also in the number of cases of diphtheria. The causes of this increase are to be sought in (1) previous illnesses predisposing to infection; (2) the localization of the infection; (3) the association with the bacillus of Löffler of other bacteria; (4) complications, especially intercurrent affections; and (5) the method of treatment. The predisposing disease in the present instance was measles, as is clearly shown in the statistical tables given, which also exhibit the marked effect it had upon the rate of mortality. Owing probably to the same cause there was an unusual percentage of laryngeal cases with a mortality of 34%. In the mixed infections (with streptococci, staphylococci, pneumococci, etc.) the mortality reached 40%. Of acute intercurrent affections, which, owing to measles, were twice as numerous as in previous years, the most deadly was bronchopneumonia (with a mortality of 70%). Anti-diphtheritic serum was employed exclusively in the treatment of all the hospital cases, but nevertheless the percentage of deaths was high, owing to delay in bringing patients to hospital and the consequent loss of time in commencing the injections. When administered on the first day of the attack, the beneficial effect of the serum is unfailing, but after the third day it has little or no power to influence the course of the disease. [G.S.B.]

2.—In the report by the *Lancet* commissioners on the conservation of vaccine lymph, April 28, 1900, it was stated that the merit of this discovery of the best method was due to Copeman, Chambon, and Saint Yves-Menard. By Doria this honor is claimed for Professor Leoni, formerly Director of the Vaccine Institute of Rome, who was the first to demonstrate that vaccine virus in the fresh state is contaminated by germs, and that these germs disappear in vaccine virus preserved with glycerin under certain conditions of temperature, after 3 or 4 weeks. Leoni's experiments determining this important fact were made, it is stated, in 1889. [G.S.B.]

Practical Therapeutics.

Smokers' Gingivitis:—

R.—Salol 1 part.
Tinct. catechu 4 parts.
Spr. menth. pip 120 parts.

M. ft. lotio. S. Teaspoonful in half a glass of tepid water as a mouth-wash.—*Indian Medical Journal, Calcutta.*

Digitalis and its Derivatives.—J. P. Arnold and H. C. Wood, Jr., *Amer. Jour. Med. Sci.*, Aug., 1900, found that:

1. Digitalin and digitoxin each represent the full circulatory powers of digitalis.

2. Digitalis, digitalin and digitoxin stimulate the cardio-inhibitory mechanism, both centrally and peripherally. In larger doses they paralyze the intrinsic cardioinhibitory apparatus.

3. They all cause a rise of blood-pressure by stimulating the heart and constricting the bloodvessels.

4. Very large doses paralyze the heart-muscle of the mammal, the organ stopping in the diastole.

5. Digitalin of Merck is a stable compound, 1 gram of it being equivalent to about 70 cubic centimeters (18 drams) of tincture of digitalis.

6. Digitoxin is not to be recommended for human medication on account of its irritant action, which makes it liable to upset the stomach when given by the mouth, or to cause abscesses when given hypodermically, and on account of its insolubility, which renders it slowly absorbed and irregularly eliminated, having a marked tendency to cumulative action.

Ointment for External Hemorrhoids.—

R.—Chrysarobin 15 grains.
Iodoform 5 grains.
Ext. belladonna 10 grains.
Vaselin 4 drams.

Use and Abuse of Potassium Iodide in Ophthalmic Practice.—Dr. Albert Rufus Baker (*The Journal American Medical Association*, November 17, 1900) comes to the following conclusions:

1. Iodide of potassium should generally be administered in rapidly increasing doses until from 1 to 500 grains are given daily.

2. The drug should always be given after eating, and well diluted with water.

3. Frequent hot baths are essential to the best results in the use of the remedy.

4. Not infrequently large doses will be tolerated when smaller ones can not be well taken.

5. The use of the large dose is not limited to syphilitic cases.

6. Large doses are indicated in optic neuritis, ocular paralysis, choroiditis, serous iritis and in relapsing iritis, cyclitis and interstitial keratitis.

7. It is contraindicated in gray atrophy of the optic nerve and in most cases of postneuritic origin.

8. Albumin in the urine, generally speaking, is a contraindication for large doses of iodide.

9. Young children do not take the iodide kindly and it should be administered cautiously.

10. The remedy is of doubtful value in early syphilitic iritis.

11. Large doses are of doubtful utility in the removal of postoperative exudates, but should be given further trial.

Diuretic in Cardiac and Renal Dropsy.—

R.—Fl. ex. jalap. } of each 4 drams.

Aqua destil 3 drams.

—*Jour. de Med. de Paris.*

The Therapeutic and Diagnostic Employment of Suprarenal Preparations in the Upper Respiratory Cavities.—

Mosse (*Die Therapie der Gegenwart*, 1900, No. 12) has employed suprarenal extract in various cases of nose and throat diseases. Immediately upon application of the remedy a local anemia takes place which lasts but a few hours. While the practical value of the remedy in these diseases is only a limited one as far as therapeutics are concerned, it is, however, of some diagnostic importance. For this purpose it can be used in conjunction with probes instead of cocain, wherever it is to be determined whether the disease of the nasal mucous membrane is due to hyperemia or to increase of tissue.

Early Cough and Fever in Pneumonia.—

R.—Potassium citrate 6 drams.
Spirit nitrous ether 4 drams.
Camphorated tincture opium 4 drams.
Solution potassium citrate, to make 6 ounces.

Dessertspoonful every 3 hours.

—*HUGHES (St. Louis Clinic.)*

The Treatment of the Paroxysmal Stage of Whooping-cough.—

Godson (*British Medical Journal*, November 3, 1900), as the result of a collective investigation, found that in the treatment of whooping-cough the drugs commonly employed and chiefly depended upon were antipyrin, belladonna, bromides, carbolic acid, creosote, and opium, while as accessory and occasionally useful drugs chloral hydrate, quinin and butyl-chloral-hydrate were mentioned. The antispasmodics are always combined with expectorants, of which the alkalies are the greatest favorites. Inhalants appear to be in general use, the ones referred to being carbolic acid, creosote, bromoform, and chloroform. None of the answers that were received were enthusiastic except from those who had used creosote. The simplest and best method of administration is to sprinkle the drug on a cloth, and hang the cloth in the sickroom or nursery to dry. The method of treatment that the author has found most satisfactory is the following: Commence at once with the continuous inhalation of creosote. Clear the lungs of bronchitis as much as possible before using any special internal antispasmodic remedies. In bronchopneumonia, however, belladonna appears at once to do good. In all cases, if or when the chest is fairly clear, and the circulation is good, antipyrin may be given in suitable doses. Expectorants should be combined with the antipyrin. Good air, warm clothing, sunlight, and wholesome food are necessary in all cases.

To Remove Cerumen.—Dr. Godart, of Lyons, recommends for the removal of pluglets of ear wax:

R.—Pure carbonate of sodium... 1.00.
Glycerin 20 c.c.
Distilled water 20 c.c.

A few drops are inserted several times a day, followed by injections of water.

Dyspepsia.—Sir T. Lauder Brunton, in the *Clinical Journal*, emphasizes the following points in instructing patients troubled with dyspepsia:

1. Eat slowly, masticate and insalivate thoroughly. And, if necessary, follow Sir Andrew Clarke's rule—count the bites.

2. Take the solids and liquids separately, so as not to dilute the gastric juice nor weaken the digestive ability of the stomach.

3. If necessary, let the patient take his farinaceous food and the proteids at different meals.

4. The best fluid is hot water, taken early in the morning and an hour or two before lunch and dinner.

a. Alkalies before meals stimulate secretion of gastric juice.

b. Acids before meals check acid secretions of the stomach.

c. Where the food remains in the stomach an unusual length of time lavage should be resorted to.

THREE DANGEROUS OPERATIONS.

Repair of Lacerated Cervix, Curettement and Rapid Dilatation of the Cervix.

By JOHN B. DEEVER, M.D.,

of Philadelphia.

Surgeon-in-Chief to the German Hospital.

THIS paper is intended as a protest against the indiscriminate use and abuse of three operations in surgery, which in themselves are excellent procedures and capable of accomplishing much good and the relief of suffering. We cannot, therefore, condemn the operations, but, as is very often the case, they are performed without due deliberation and knowledge of the indications and contraindications.

Curettement, rapid dilatation or divulsion of the cervical canal and repair of a lacerated cervix call for mature judgment and skill for their instigation and performance. It would be difficult to say from which one of the three the greatest amount of harm has accrued, probably from curettement, although divulsion is very frequently followed by untoward symptoms.

A lacerated cervix in women who have born children is so common that it may be considered as more of a normal than pathological condition. In the absence of special indications, such a cervix had better be let alone, for to operate under these circumstances subjects the patient to useless risks without a commensurate reward.

If, however, a lacerated cervix be extensive enough to permit gapping of the edges and consequent exposure of the cervical mucous membrane to injury, or if ulceration be present, or if the scar-tissue is hard and in excessive amount, or if any of these conditions give rise to subinvolution or marked reflex symptoms, then operation is indicated. If, in addition to any of the above conditions, there is a history of hereditary tendencies toward malignancy, we have the strongest indication for operation. A patient with a family history of carcinoma presenting the above conditions should, in my opinion, be operated upon at the earliest possible moment, and this should be repeated after subsequent labors if the cervix be again torn, as it is likely to be.

As strong as these indications are for operative interference, we are not justified in instituting them unless there is freedom from all pelvic inflammatory processes or their results. Salpingitis, pyosalpinx or adhesions offer strong contraindications.

Under these circumstances, abdominal section for the correction of the intraabdominal trouble should follow immediately the repairing of the lacerated cervix. If the cicatricial tissue in a lacerated cervix involve the supravaginal cervix, it may be sometimes impossible to remove it entirely except by high amputation of the cervix with freeing of the bladder and rectum; if under these circumstances there is a history of a hereditary tendency to malignancy, or if the patient be near or undergoing the menopause, vaginal hysterectomy may be considered the more rational procedure.

In the presence of endometritis, great care must be exercised to prepare the endometrium if this be possible prior to the narrowing of the cervical canal, so as to provide adequate drainage, or in other words, to decrease the discharge so that the new and narrow canal will carry it off.

Equally as important is it to carry out every aseptic detail during the operation and antiseptic preparation of the field of operation in any one of the three operations under discussion, as it is in any in the realm of surgery.

That these operations are capable of converting a latent salpingitis into an active one, every abdominal surgeon of experience can testify. It can be brought about in one of several ways; first and most important, by the introduction of sepsis through instruments or intrauterine douching, or the spread of sepsis from an infected uterine cavity, or by the breaking up of peri-uterine adhesions, liberating septic foci which have been imprisoned.

Adhesions can be torn by bringing the uterus down to the vulvar orifice; the tenaculum should only be used to steady the uterus and not to make traction during dilatation or repairing of the cervix.

Washing out the uterus, except in septic conditions, also plugging the uterine cavity with iodoform gauze, I regard as vicious practices, which in themselves are too often capable of exciting inflammation in the fallopian tubes. Even in septic conditions of the interior of the uterus, the intrauterine douche should be very carefully done and the packing introduced for the purpose of drainage and not to its exclusion. Curettement of the uterine canal is a dangerous operation and one which calls for great delicacy of touch and the most rigid observance of aseptic and antiseptic details. The indications for its performance are positive, although one should never forget the contraindications.

The indications are for the correction of septic conditions of the cavity of the uterus, both acute and chronic. In the acute form of endometritis, which is post-puerperal infection as a rule, we curet with propriety; to remove retained foreign matter, we must beware of the great danger of uterine perforation, an accident which can and does happen with the most startling ease. In chronic endometritis curettement, the persistence of the disease and the constant danger of tubal infection and peritonitis, or lymphatic infection and peritonitis, makes it an operation of wisdom in many cases. We should, however, have in mind the likelihood of the lightening up of a latent salpingitis, or latent sepsis in some other locality and be prepared to complete the operation by removal of the foci of pelvic inflammation.

If the discharge arising from an endometritis shows the presence of gonococci, curettement is positively contraindicated, for it is certain that such a procedure will most probably lighten up an active gonorrhea which shows marked tendency to spreading and consequent tubal involvement.

When the indications for curettement are established, then the operation should be done with an intelligent thoroughness which will leave no portion of the cavity untouched by the curet. The so-called moral effect of an operation accomplishing good, I think is bosh; certainly any improvement is but temporary. Again I think the supposed curative effect of operations *per se* should be relegated to the absurd dogmas of the Christian Scientists. If the surgeon by logical reasoning cannot arrive at the conclusion to operate in a given case, then he had better let it alone; an operation should be attempted only to remove an existing pathological condition, and not one which is simply supposed to exist, or which might exist.

There is a doubt in my mind as to the reliability of

the information derived from an examination of specimens curetted from a uterine canal in which malignant changes are suspected. It is very difficult to make a positive diagnosis, oftentimes, between chronic benign lesions of the uterine mucous membrane and early malignant changes; and then the specimens are necessarily small and fragmentary and interfere with a satisfactory examination.

The advantage of such knowledge, when reliable, is inestimable, but nevertheless it can only serve as an adjunct to the clinical diagnosis and must of necessity play a secondary part. The ability to make a diagnosis from a curetted specimen is only acquired by a highly specialized training of brain, eye and fingers.

In advanced carcinoma of the cervix, where other and more radical measures are impossible, curettement followed by the application of the cautery is indicated and will lessen the patient's discomfort.

Flexion of the uterus combined with endometritis in the absence of adhesions indicates dilatation followed by curettement.

Dilatation of the cervical canal is an operation which offers a fruitful field for the ambitious surgeon. It is devoid of cutting and is practically bloodless and therefore appeals to a patient. If it was not so dangerous and inefficient, I might be induced to sanction it and perform it more often than I do. Recently America's greatest gynecologist said to me that a dilatation of a cervix caused him greater anxiety for the first days following an operation than would a bad pus section or hysterectomy.

Slow dilatation by sponge tents, even though protected by a sterilized rubber cot, or by gauze or sponge packing, offer, no advantages over divulsion and is attended by much greater risks of sepsis. I would especially condemn the attempts, and I say attempts advisedly, to dilatation in the physician's office, as it is a most dangerous and useless practice. Divulsion should never be done except under complete anesthesia and with the most rigid observance of aseptic and antiseptic precautions. Antiseptic preparation of the vagina is as important here as it is for a vaginal hysterectomy; the vulva should be shaved, and the vulva and vagina after preparation should be protected by iodoform or sterile gauze. The operator and all assistants and nurses should wear sterile rubber gloves.

Dilatation is indicated in dysmenorrhea due to cervical stenosis, as a preliminary step to curettement when there is a displacement of the uterus which is not adherent, and when there is an absence of pelvic or tubal inflammation, either active or latent.

Divulsion for stenosis of the cervix is at best an unsatisfactory measure, as it frequently fails to meet and overcome the condition. It is often necessary to repeat the operation several times before relief is afforded. After the first divulsion, in addition to the stenosis, we have the rigid scar-tissue to deal with, and here it is comparatively easy to lacerate the cervix.

Frequently relief is not experienced at the first menstrual period following the operation, so that we should not be too hasty in repeating the measure, but should wait until the evidence of failure is positive.

Dilatation as a method for the correction of flexions of the uterus must be classed among the surgical failures. I have never been able to satisfy myself that it has accomplished the slightest bit of good.

Upon the recognition of one condition, an infantile uterus in a woman suffering from dysmenorrhea will

or should demonstrate the futility of attempting to restore a cervical canal by dilatation in an organ which is congenitally defective. Operation under such circumstances is always attended by failure, because the source of the trouble is the result of the abnormality of the uterus itself or in conjunction with its adnexa. This is also true of the other congenital malformations of the uterus, viz., the bicornate uterus, etc.

We have tried to point out the various dangers and possible contingencies which may arise in the performance of these three operations, and in a general way to show the methods to overcome them and to carry the procedures to a successful issue.

For the sake of emphasis, allow me to run over the points again.

First of all, the antiseptic preparation of the field of operation; the vulva should be shaved and prepared by soap and water, permanganate of potash and oxalic acid, bichloride of mercury, and carbolic acid solution, and protected by a pad of sterile gauze. The vagina by the use of soap and water, bichloride, and carbolic solution and iodoform gauze packing. During the operation every rule of aseptic detail must be adhered to; sterile instruments and gauze, linen, blankets, etc., and hands protected by sterile rubber gloves.

I am a firm believer in rubber gloves, because they not only diminish the risk of infection, but they protect the surgeon; you cannot boil the hands, but you can boil gloves, and thus be sure of the only absolutely reliable method of sterilization. If it be necessary to simultaneously perform a vaginal operation and abdominal section, it is very easy to change gloves and thus be sure of sterility.

This leads me to a renewed warning in regard to operations on the cervix or its canal in the presence of a latent or active inflammation or adhesions binding the uterus down. As has been said, it is the part of wisdom to correct both conditions at the same time.

By the repeated performance of surgical operations, and the consequent attention to aseptic precautions, one develops a habit of being surgically clean, and it seems to be a fair proposition that such a habit will insure a greater degree of success than can be expected by the estimable gentlemen of our profession who operate occasionally, and who are in constant contact with those diseases which have a special predilection toward sepsis and septic infection. I would therefore advise that these three operations should be confined to the realm of surgery, and not be classed as work which is the duty and prerogative of the general practitioner of medicine.

ON THE DESIRABILITY OF COMBINED OPERATIONS IN PELVIC AND ABDOMINAL SURGERY.¹

By W. P. MANTON, M.D.,
of Detroit, Mich.

Professor of Clinical Gynecology, and Adjunct Professor of Obstetrics, Detroit College of Medicine; Gynecologist to Harper Hospital, and to the Eastern and Northern Asylums for the Insane; Consulting Gynecologist to St. Joseph's Retreat; Vice-President Medical Board Woman's Hospital and Infants' Home, etc., etc.

TWENTY-FIVE years ago, when pelvic surgery was yet in its swaddling clothes and the *terra incognita abdominalis* was just opening up new fields to the adventurous, all operations along the sexual tract were viewed with

¹ Transactions of Third Pan-American Medical Congress, Havana, February 4-8, 1901.

interest, while an abdominal section was recognized as an event of no little importance.

The advent of Listerism and the subsequent evolution of aseptic surgery revolutionized methods and rendered undertakings possible which, theretofore, had hardly entered into the wildest speculations of the ultra-radical, until today, from the accumulated experience of the past, nearly every part and organ of the body may be invaded with greater or less impunity. In reviewing the history of the development of abdomino-pelvic surgery during the quarter century just closed, however, while one cannot but be filled with admiration at the great advancement made and the wonderful results accomplished in this particular line of work, the question naturally intrudes itself, Have the achievements of the immediate past led to an overboldness of action, and has enthusiasm and the confidence begotten of fancied security in anesthesia, asepticism and technic betrayed into the overlooking or ignoring of the best interests of the afflicted individual?

The patient resorts to the surgeon with one object in view, the relief of somatic suffering or inconvenience, and expects from him honest dealing in the accomplishment of this end. Does the surgeon, therefore, fulfil his duty to the patient if he but partially effects the service which he is expected to render?

There is, I feel sure, no one of experience but will answer these questions in the negative and point to facts for corroborating evidence. Assuming then, that the surgeon undertakes only that which he is authorized to do for the patient's good, in his endeavor to bring about the results desired, how much is he justified in attempting, and how may he determine the limit at which safety ends and danger begins to assert itself; the point where benefit shades into positive injury?

Among gynecological patients it is usual to find not one, but a number of abnormal conditions or defects present, each of which has a definite bearing on the individual's health and comfort, and demands a distinct operation for its relief or cure. Shall these various conditions be attacked successively at the same sitting, shall the different operations be performed at intervals, or shall certain parts be restored while others are left untouched? Clinical experience and pathology have taught that the best results cannot be awaited from the attempted restoration of one surgically diseased part when lesions of associated structures are allowed to continue undisturbed; in other words, in associated morbid conditions, the harmony and adjustment of all the disordered elements must be collectively reestablished in order to bring about the perfect restoration of the individual defect. Obviously, then, if we are to effectuate the charge placed upon us by the patient, the combined operations indicated must be carried out in order to fulfil the requirements of the case, and this is, I believe, the practice of most operators at the present time.

By the unfamiliar, however, the performance of several operations at the same sitting is often looked upon with astonishment and doubt, and frequently censured as unwarrantable, the onus, in the event of untoward result, being visited upon the surgeon.

In order that this question may be definitely settled by weight of authority, so seemingly unimportant a subject is brought to the attention of this congress.

In summing up the evidence in favor of combined operations it may be said, experience has demonstrated on the one hand, that several operations performed at

the same sitting do not compromise the life of the patient to any appreciable degree; that the extra time, within reasonable limits, required for the execution of the various procedures does not necessarily augment the dangers to be anticipated from any surgical act; that repair in the individual parts involved goes on as uninterruptedly and successfully and that convalescence is as rapid and satisfactory as when but a single uncomplicated operation is performed. While, on the other hand, following the passing of the ordeal, the patient's mind remains tranquil and undisturbed by the dread of possible future treatment and the fear of the anesthetic, convalescence is not retarded by the presence of morbid structures or conditions left behind, and recovery is not partial but total and complete.

In the opinion of the writer, therefore, in every instance, whatever is necessary should be done, whether the conditions lie within the pelvis, the abdomen, or both; and the limit of execution should be gauged only by the general condition of the patient, her behavior under the anesthetic, and the inherent dangers of the operations to be performed. These, together with experience, skilful operating, strict asepticism and watchful care of the patient, are the *sine qua non* of success.

URINARY HYPERACIDITY.

A Consideration of Cases with Symptoms Suggestive of Cystitis, But With No Infection, Due to This Cause.

By THOMAS R. BROWN, M.D.,

of Baltimore, Md.

Chief of Clinic, Johns Hopkins Hospital Medical Dispensary; Associate Professor of Clinical Medicine, College of Physicians and Surgeons.

It is of course a well-known fact that certain symptoms of cystitis are found in a variety of other conditions in which there is no vesical infection. Thus, increased frequency of micturition either alone or associated with somewhat burning, slightly painful micturition is noted during the use of a number of drugs, such as copaiba, cubebs, camphor, salicylic acid, cantharides in small doses (large doses bring about acute cystitis), etc., etc., and also during the course of many fevers due perhaps to the noxious substances eliminated, perhaps to the increased concentration of the urine. There is also a well-recognized series of cases in which the symptoms are distinctly referable to certain pathological conditions in the organs and tissues adjacent to the bladder. Thus, a marked relaxation of the vaginal outlet, the presence of large uterine myomata or ovarian cystomata, a condition of pelvic peritonitis due to a variety of conditions with the formation of adhesions between other organs and the bladder, these and other conditions tend to produce an irritated or congested condition of the bladder which in its turn is productive of somewhat frequent and occasionally painful micturition, often associated with the presence of a few pus or red blood-cells in the urine.

The cause of the urinary symptoms, however, in all these cases is easily recognizable and the symptoms may be abated by proper attention to the causative agents; thus in the former series of cases the condition disappears with the cessation of the special form of medication, while in the second series of cases the removal of the offending tumor, the separation of adhesions, the lifting up of the relaxed outlet, or the

removal of a protruding uterine polyp will cause a complete cessation of the symptoms.

There is, however, another class of cases in which no definite cause for the suggestive symptoms other than a general neurasthenic or neuropathic tendency can be given, and it is in reference to a certain class of cases of this nature that this communication will treat. In these cases the vesical irritability is produced by a distinct hyperacidity of the urine, and so far as I know this is the first communication in which this has been shown beyond a doubt to be the etiological factor in the production of such a condition. In connection with my bacteriological study of the infections of the bladder, I was frequently struck by the fact that many of the symptoms of cystitis, frequent burning micturition often associated with the presence of a few pus or red blood-cells in the urine, was found in a certain class of cases where a study of the urine demonstrated that there was no infection present. In testing the reaction of the urine in the first of these cases that was presented to my observation, it was noted that the blue litmus was colored an extremely bright red. It was therefore regarded as possible that the symptoms might be directly referable to an increase of the acid or the acid salts in the urine; this hyperacidity in turn producing a distinct irritation of the vesical mucous membrane and the symptoms already mentioned. To determine this definitely, I have made a quantitative determination of the total acidity of the urine in all cases presenting such a symptom-complex without any definitely assignable cause. The method I have employed has been the titration of 10 ccm. of the freshly catheterized urine with a one-tenth normal solution of sodium hydroxid, phenol-phthalein being used as an indicator. Although this method is not quite so exact as the more complicated one of Freund, where the estimation is based upon the quantitative determination of the acid phosphates present, nevertheless it is comparatively quite exact and furnishes us with a fairly accurate criterion of the total quantity of acids and of acid salts present in a given quantity of urine.

A series of normal cases was also taken to determine the average acidity of normal urine which we have designated as 10. Since the inception of these estimations, 9 cases have been met with, in all of which the symptoms were distinctly referable to a hyperacid condition of the urine. All these cases presented the characteristic symptom-complex, although the symptoms were much more marked in some cases than in others; all complained of frequent, painful burning micturition of greater or less extent; in the more marked cases quite sufficient to absolutely simulate a true cystitis and frequently to have deceived the attending physician into believing it to be of such a nature.

A cystoscopic examination in all the cases in which it was made showed a marked injection and hyperemia of the trigonal area in the bladder, in some cases of a maximum degree, and sometimes in these cases associated with a lesser hyperemia of the mucous membrane adjacent to that of the trigonum; these latter cases were those in which the symptoms so completely simulated those of a true cystitis.

The urine always contained pus cells, usually in very small number, although occasionally quite a considerable number were present, a few red blood-cells and some bladder epithelial cells; cultures of the urine were always sterile. In many of the cases the upper portion of the urethral mucous membrane was injected.

The acidity of the urine in these cases, determined by the method described above, and upon the basis of 10 as the normal acidity, was respectively 27.5, 30, 20, 31, 30, 49, 21, 31, 29; that is, in all these cases the acidity was at least twice, and in one, nearly five times as great as normal. It was also a noteworthy fact that the gravity of the symptoms, the degree of the injection of the trigonum, and the number of pus and red blood-cells present in the urine stood in direct relationship to the degree of the acidity. Thus in those cases in which the acidity was 49, 31, 31, and 29, the symptoms were such as to distinctly simulate a true acute cystitis of an infectious nature; the frequency of micturition was so great as to necessitate urination every 1 to 3 hours during the night, and $\frac{1}{2}$ to 3 hours during the day, while the painful and burning sensation in these cases was very marked. In several of the cases, the patients definitely localized their pain in the trigonal area of the bladder, and in the upper portion of the urethra. Four of this series of cases had been definitely diagnosed by their physicians as cases of cystitis, and had been sent so us for treatment for that condition. There was no local pelvic trouble whatever in any of these cases.

Although the increased acidity seemed to be the undoubted local cause of the condition, the cases were carefully considered to see whether some general cause could not be found which in turn could account for the hyperacidity. Obviously because of the chronic character of these conditions, peculiarities of diet could not be regarded as a cause, and this was also shown by the very slight effect that different varieties of diet seemed to have upon the symptoms. It was noted, however, that all of these cases occurred in young girls, or in young married women, in all of whom there were marked neurasthenic, neurotic, or hysterical manifestations, and in many distinct stigmata of these conditions. It was also noted by the patients themselves that anything which tended to render them more nervous, such as prolonged excitement, prolonged mental or physical strain, or violent emotional disturbances, markedly increased the symptoms, while if the life they led bordered upon one of extreme simplicity, the symptoms were much ameliorated. The result of the treatment of these cases also justified us in the belief that, although the vesical symptoms were distinctly referable to the urinary hyperacidity (probably somewhat increased by the increased irritability of the bladder, as well as all the other organs seen in neurotic or neurasthenic conditions), the hyperacidity in turn was directly referable to the general neurasthenic, neurotic, or hysterical condition; in other words, this hyperacidity was a urinary neurosis of neuropathic origin. The treatment was designed thus both to counteract the local hyperacidity of the urine and to correct as far as possible the underlying neurosis, neurasthenia, or hysteria. For the first, alkalies were administered by mouth in sufficient quantity to render the urine neutral or alkaline; in some cases a comparatively small amount of alkali was all that was required for this purpose (potassium citrate or potassium bicarbonate, 15 to 20 grains, 3 times a day); in other cases, however, the hyperacidity was so great that the administration of as much as 100 grains of the alkali daily was necessary to render the urine neutral; to correct the general condition, the usual treatment of rest, freedom from excitement, plenty of sunshine and fresh air, overfeeding, and a general attention to all the various bodily functions was carried out. Strychnia was administered in most of the cases, while in some a

veritable rest cure, associated with cold packs and massage, was found to be necessary.

In the 4 cases in which this treatment was carried out in full the symptoms disappeared quite rapidly; it is highly probable, however, if the patient relapses into her previous neurotic condition, that the symptoms, both local and general, will reappear. This was definitely seen in one case who was entirely free from all symptoms for 6 months subsequent to the cessation of the treatment, when, after a prolonged course of excitement and social dissipation, the symptoms returned, although less marked than when seen the first time. The patient was placed upon the same line of treatment as before and the symptoms rapidly abated.

In considering this neurosis of urinary secretion, it was thought probable that it was, in a certain way, analogous to the gastric hyperchlorhydria which is often associated with hysteria. Although, of course, vesical irritability in neurotic individuals has been described frequently, hitherto, so far as I know, the determination of urinary hyperacidity as an etiologic factor has not been described before.

I have dwelt upon this condition not only because of the interest attached to any of the secretory neuroses that are met with, but also, and perhaps mainly, because of the absolute necessity of correctly diagnosing the condition. If the condition is correctly diagnosed, proper medical treatment can bring about a complete cure in the majority of cases without any local treatment of the bladder whatsoever; if, on the other hand, a wrong diagnosis is made, and the condition is regarded as a cystitis and treated as such, often a real infection of the bladder will be set up by the long-continued use of irrigations and local applications, that are so usually employed, and the second state of that woman will be much worse than the first. To show that this is no idle warning, I need simply mention that at least 5 of the cases of chronic cystitis that have come under our observation owe their origin to the misinterpretation of this condition. Two of these cases were in young girls and, in them both, the cystitis which was directly consecutive to the treatment for what was undoubtedly but a simple case of vesical irritability probably due to urinary hyperacidity, was of so serious a nature that life had been rendered practically unbearable in both cases for many years, while the bladder now is in such a condition of ulceration and contraction that a cure, if it is obtained at all, will only be reached after the most protracted and painful course of treatment.

CASES WITH SYMPTOMS OF CYSTITIS BUT NO INFECTION, DUE TO HYPERACIDITY OF THE URINE.

CASE 1.—Hysterical young woman, extremely nervous, teaches school and has to be on her feet most of the time; condition persisting for 3 years, always getting markedly better during her vacation. Symptoms: At first, only frequent desire to urinate, later (for past year) pain and burning sensation in bladder. Symptoms are aggravated by cold, overexertion and nervous strain. Examination: Trigonum deeply injected; right floating kidney. Urine: A few pus cells and epithelial cells, no albumin, extremely acid (acidity, 27.5). Bacterial examination: Sterile. Treatment: Alkalies by mouth; hygiene; rest cure. Result: Cured. Patient seen 6 months later, has no trouble of this nature; whenever any tendency towards frequent urination appears, takes alkalies by mouth and rests more and condition is relieved.

CASE 2.—Neurasthenical woman of 28, with many hysterical manifestations. Symptoms: Scalding and frequent urination for past 6 or 7 years with pain in bladder. Examination: Intense hyperemia of trigonum and upper

urethra. Urine: A few pus cells and epithelial cells, occasional red blood-cells, no albumin, very acid (acidity, 30.0). Bacterial examination: Sterile. Treatment: Alkalies by mouth; cold packs, hygiene, rest cure, scarification of trigonum.

CASE 3.—Intensely neurasthenical married woman of 38, with myomatous uterus, retroflexion of uterus, and right floating kidney, and nervous gastritis with hyperchlorhydria. Bladder showed intense reddening of trigonum. Urination was frequent and somewhat painful (in mouth of urethra). Urine: A small number of pus cells, no albumin, very acid (acidity, 20), specific gravity, 1.005, very pale in color; sterile. Treatment: Myomectomy, suspension of uterus, double salpingectomy. Subsequently hygienic treatment, alkalies by mouth. Result: Symptoms entirely disappeared for more than 6 months, when the patient attempted to do too much, when the symptoms and hyperacidity returned. She was given the rest cure with alkalies by mouth and the symptoms again disappeared.

CASE 4.—Nervous woman of 31, complaining of nervousness, headache, and pain in the back of the neck, and painful and frequent micturition (urinates 4 to 5 times at night), and irritable bladder. Examination: Hyperemia of trigonum. Urine: A few pus cells, no albumin, very acid (acidity, 31.00), sterile.

CASE 5.—Complaint: Irritable bladder and frequency of micturition. Examination: Injected trigonum. Urine: Occasional pus cells, no albumin, very acid (acidity, 30.0); sterile.

CASE 6.—Married woman of 25, very neurotic. Three years ago, six days after marriage complained of frequency of urination, and later also of a tender spot in the bladder and dysuria. These symptoms have continued since then, and the patient has had the urethral sphincter dilated, the tender spot touched with various substances, and the bladder washed out. Examination: Intense scarlet injection of the trigonum, especially on left side. Urine: A few pus cells, occasional red blood-cells, no albumin, intensely acid (acidity, 49.0); sterile. Treatment: General hygienic treatment, touching spot with silver nitrate, alkalies by mouth (it required 100 grains of potassium citrate per day to render the urine neutral or alkaline). Result: Marked improvement (patient still under treatment).

CASE 7.—Married woman of 33. Severe instrumental delivery three years previously, since which time she has frequently used the catheter to withdraw her urine. During this time she has had considerable pain on urination, increased by cold, with a severe attack of vesical pain with fever two years ago. Examination: Deep injection with some ulceration at vertex of bladder. Urine: Very occasional pus-cells, no albumin, very acid (acidity, 21.0); sterile.

CASES 8 and 9.—Office patients seen but once, each complaining of frequent and somewhat burning micturition, and in each of whom cystoscopic examination revealed a deeply injected trigonum. Urine: A few pus cells, no albumin, very acid (acidity of Case 8, 31.0; acidity of Case 9, 29.0); sterile.

MULTIPLE BRAIN ABSCESS FOLLOWING EMPYEMA.*

By THOMAS A. CLAYTOR, M.D.,

of Washington, D. C.,

Professor of Clinical Medicine, Columbia University; Attending Physician to Garfield Hospital, etc.

JUSTIFICATION for this report is sought, first, in that brain abscess from pulmonary disease is not very common, and secondly, in that while an abscess may be caused by disease of either lung or pleura, it more usually results from the former.

H. P., male, aged 22, was first admitted to the Garfield Memorial Hospital on May 26, 1899.

The patient had had the usual diseases of childhood, and typhoid fever 5 years before admission. While in Cuba during July, 1898, he contracted malaria, from which he thought he had never fully recovered. In September of the same

* Read before the Medical Society of the District of Columbia, November, 1900.

year he began to have a dull pain in the left side, which had not left him. A short time before admission (date not noted), he awakened one morning with a sharp, piercing pain in the left side, which was increased by motion and inspiration. He had a slight chill, and a dry cough set in.

On admission the temperature was 100.4° F., pulse 120, respiration 52. Dyspnea marked, pain in cardiac region severe. The expression was anxious, and there was slight cyanosis. The tongue was lightly coated. The vessels of the neck pulsated visibly, and there was marked pulsation in the third, fourth, and fifth interspaces on the right side of the sternum, which could be seen as far out as the right nipple line. No pulsation could either be seen or felt to the left of the sternum. Anteriorly, on the right, dullness began at the third rib and extended downward into the liver and toward the right for 3 inches from the midsternal line. On the left dullness began at the third rib and extended downward to costal border. The axillary region was so exquisitely tender as to render examination by percussion impossible. Posteriorly the flatness extended from 2 inches above the angle of the left scapula to the base of the lung. The upper level of the dullness was but slightly, if at all, altered by change of position.

The heart-sounds were distinct over the sternum, but were very faint at the normal position of the apex. The respiratory sounds were harsh over the right lung, and over the apex of the left, becoming tubular over the normal position of the heart. There was also tubular breathing over the area of flatness posteriorly. The diagnosis of left pleural effusion was made. The patient's condition was such as to demand immediate relief. Therefore, on May 27, paracentesis was performed in the seventh interspace midaxillary line. There seemed, however, to be some obstruction to the flow, and only a small amount of straw-colored fluid was drawn off. No cultures were made. The patient experienced slight relief, but two days later his suffering was so intense that I requested my colleague on the surgical side, Dr. A. A. Snyder, to see him. We decided it would be best to attempt paracentesis again and, failing in that, to incise and drain.

I will here anticipate criticism by saying that we were fully alive to the great probability of converting a serofibrinous pleurisy into an empyema, but the patient's condition was so serious that it seemed to be but a choice of evils, the left chest being nearly full of the exudate, and the heart pushed over until it occupied the position on the right, which it normally occupied on the left. There was extreme pain in the cardiac region, with cyanosis and dyspnea.

Dr. Snyder found it necessary to resort to incision. It would seem likely from the facts that the fluid came in such small quantities through the canula and so slowly even through the drainage tube, that there must have been adhesions which allowed the fluid to escape with difficulty. The following day the patient was more comfortable, the temperature and pulse had fallen, but the respirations were still frequent. For four days the condition was somewhat improved, the temperature not rising above 100.8° F. The fluid also gradually decreased, draining slowly into the dressing. The pain in the left side and over the præcordia, however, was so intense as to require morphia almost constantly. On June 1 the fever increased, took on the hectic type, and it was found that the wound had become infected. Two weeks later an empyema having developed, Dr. Snyder under chloroform-anesthesia made a 3½-inch incision over the seventh rib midaxillary line on the left side. After dissecting the periosteum away a 2-inch section was removed without injury to the intercostal artery. The pleural sac was opened and a large quantity of thin pus was evacuated. After flushing with hot salt-solution a tube was introduced and the wound partially closed with silkworm gut. Improvement was marked and the course of the case uneventful until June 24, when the temperature again went up and became hectic in type. This condition of affairs went on until September 20, when Dr. J. Ford Thompson performed the Estlander operation, resecting portions of the fifth, sixth, and seventh ribs in the midaxillary line. The seventh rib which had been resected minus the periosteum by Dr. Snyder had reformed. Quite a large pus pocket was evacuated and free drainage instituted. In three days the temperature fell to normal and the general condition rapidly improved. The patient was discharged on November 15, 1899, practically cured, except for a small sinus which he

returned to have dressed every few days. His condition was excellent, flesh was rapidly gained and he began to drill at the armory.

On December 9, H. P. was again admitted, complaining of having had on December 6, three days before, a chill associated with headache, high fever, nausea, and profuse sweating. On December 8 there had occurred a second chill, fever, headache, etc. Since that the pain in his head had not left him and was described as being intense, extending over the entire cranium and down into the back of the neck. Vomiting occurred whenever food was taken. The bowels were constipated. Temperature was 103.2° F., pulse 120, respirations 24. The patient was admitted to the surgical side with the idea that the existing condition was due to a reaccumulation of pus in the chest, but as Dr. Thompson was not positive upon this point he requested me to see the case daily until we could come to a definite conclusion.

Examination showed a flushed face, anxious expression and a clean tongue. The heart-sounds were normal and the organ had returned to its normal position. The left side of the chest was shrunken somewhat and the signs indicated a much retracted lung. The spleen was enlarged and there was abdominal tenderness. The urine showed a specific gravity of 1.031, acid reaction, albumin one-third by bulk and a few hyaline casts. The usual remedies for headache failed to relieve. Morphia produced sleep.

December 11.—Headache intense, nausea continuous. Temperature, 100.2° to 103°.

December 12.—Delirious, refused nourishment, vomited frequently. Ice-cap gave no relief to intense headache. Temperature, 100° to 102°; pulse, 70 to 80.

December 13.—Wildly delirious, tried to get out of bed, headache severe, sweating freely. Temperature at 8 P.M., 98.4°; pulse, 80; respirations, 26.

December 14.—Patient seemed much worse. Temperature, 104.4°. There was for the first time rigidity of the neck. Death occurred at 3.40 P.M.

During the attack there was no paralysis, no strabismus, no inequality of the pupils. Unfortunately there was no ophthalmoscopic examination.

The autopsy showed multiple abscess of the brain, a very small area of basal meningitis, parenchymatous nephritis and beginning degenerative change in the liver-cells.

The foregoing history well illustrates an insidious onset and rapid progress to a fatal result, which is by no means uncommon in cases of brain abscess.

The left pleural cavity was entirely obliterated except for a small sinus leading backward from the opening in the side for about 3 inches. This sinus seemed to be quite clear of any discharge save a thin seropurulent fluid. The adhesions were so firm in the neighborhood of the resected ribs as to require the use of a knife to separate the lung from the ribs. From about the sixth rib downward the diaphragm was adherent to the costal pleura, but could be easily separated.

The left lung was congested and felt solid, containing but little air. The right lung appeared to be in a normal condition.

The pericardium contained about 100 cc. of clear straw-colored fluid. The heart was large but very soft and flabby. Upon the mitral valves there were a few very minute areas which macroscopically suggested a beginning endocarditis.

The stomach and intestines were much distended but showed nothing worthy of note. The liver was pale and rather soft but no abscesses were found. The spleen was much enlarged, dark and friable and was adherent to the diaphragm and ribs.

The kidneys were very large and deeply congested.

Upon the removal of the calvarium the meninges were found to be deeply congested, but there were no signs of a meningitis upon the vault. In removing the brain as the optic nerves were being severed, yellowish-gray pus gushed out from the middle fossa. Upon turning the brain upon its superior surface and pressing upon the temporal lobes pus welled out of a ragged opening in the inferior surface of the right temporal lobe. Shaving away thin sections of this lobe disclosed the fact that the ventricles were enormously distended with pus. The velum and choroid plexuses were swollen, congested and covered with pus. The excessive pressure in the ventricles had evidently caused the pus to burrow through the right temporal lobe and show itself in the middle fossa of the skull.

The brain tissue was then freely incised and numerous abscesses varying in size from a small shot to an olive were found. The abscesses were far more numerous in the frontal than in the middle and occipital lobes, which probably accounts for the late appearance of symptoms. None was found in the pons nor in the cerebellum. The only indication of basil meningitis was about the optic commissure.

The cerebral tissue was soft, deeply congested and moist in many areas of varying size. Especially was this the case in the neighborhood of the larger collections of pus. The staphylococcus pyogenes aureus and streptococcus pyogenes were found associated in the pus from the abscesses and also in blood from the heart cavities.

Dr. J. B. Nichols, pathologist to the Garfield Hospital, has furnished me with the microscopic findings in the kidneys, spleen and liver.

The kidneys showed a marked and typical condition of parenchymatous degeneration or cloudy swelling. The epithelial cells of the secreting portions of the uriniferous tubules were swollen, granular, and showed indistinct outlines and their nuclei were absent. The remaining structures were normal. The spleen was practically normal. The liver cells showed a moderate degree of cloudy swelling, their nuclei not staining as deeply as normally and the cells being in places somewhat swollen.

There seems no reason to doubt that the abscesses in the brain were metastatic from the old empyemic fistula. Why abscesses should form in the white matter of the brain and not in the other organs, as the spleen, liver, kidneys, etc., is difficult to explain. There is, however, in these cases but little tendency to the general pyemic state. As to the frequency with which abscess of the brain becomes a complication of lung disease, we read that of 76 cases of brain abscess collected by Gull and Sutton, "Reynold's System of Medicine," Vol. 2, page 568, there were 9 due to disease of the lungs or pleura. Of these 3 resulted from empyema.

The following list of 58 cases of brain abscess resulting from primary lung disease, shows that empyema as a cause is second only to bronchiectasis.

1.—Bronchiectasis, 20 cases.

Three cases reported by Naether, *Deutsch. Arch. f. klin. Med.*, 1883-84.

One each by Holzhausen, Meyer, Oppolzer, Bath, Hutchinson, Curshmann, Löhmman, and four by Biermer, quoted by Fuchs, "Gehirnabscesse nach primären Lungenleiden."

Two by Pfungen, *Wiener med. Blätter*, 1883, p. 181.

One by Sainbury, *Lancet*, October 12, 1889.

One by Caley, *Trans. of the Path. Soc.*, London, vol. 35.

One in the *Jahr. d. Wiener K. K.*, 1895, p. 456.

One by R. T. Williamson, *Med. Chronicle*, Manchester, 1893-94, p. 423.

2.—Empyema, 10 cases.

One case by Nather, *loc. cit.*

One by Almgren (von C. H.), *Schmidt's Jahrbücher*, vol. 207-208.

Two by Gull and Sutton, *loc. cit.*

One by Bettenheim, *Deutsch. Arch. f. klin. Med.*, 1884.

One by Chapt (Jos.), *Bull. de la Soc. Anatom. de Paris*, 1892.

Three by Hadden (W. B.), *St. Thomas' Hospital Reports*, vol. 17.

My own case.

3.—Purulent bronchitis, 9 cases.

Two by Nather, *loc. cit.*

One each by De Caines, Peterson, Senator, and Meyer and three by Pontoppidan, quoted by Fuchs, *loc. cit.*

4.—Gangrene, 7 cases.

Naether, two, *loc. cit.*

Huguenin, one, *Ziemssen's Cyclopaedia of the Practice of Medicine*, vol. 12.

Virchow, Meyer, Hoffmann, each one, quoted by Fuchs, *loc. cit.*

Brettner (H.), one, "Ein Fall von Gehirnabscess und Lungengangrän."

5.—Tuberculosis, 5 cases.

Meyer, Biermer and Robertson, each one, quoted by Fuchs, *loc. cit.*

Gull and Sutton, one, *loc. cit.*

Fagge, one, quoted by Williamson, *loc. cit.*

6.—Lung abscess, 3 cases.

Böttcher and Virchow, one each, quoted by Fuchs, *loc. cit.*

Steesse, one, *Med. and Surg. Report*, Presbyterian Hospital, 1898, 3.

7.—Pneumonia, 2 cases.

Bamberger, one, quoted by Huguenin, *loc. cit.*

Finley and Adami, one, *Montreal Med. Jour.*, 1893-94.

8.—Gunshot wound of lung, 2 cases.

V. Mosetigsmorf, one, quoted by Fuchs, *loc. cit.*

Esbridge and Parkhill, one, *New York Med. Jour.*, 1895, lxii.

One point which is of considerable interest from a prognostic point of view, is whether in these cases the abscess is more likely to be single or multiple.

We read in Allbutt's "System of Medicine," p. 363: "Abscess of the brain is a consequence, not very uncommon, of empyema. The abscess is usually single and occupies either the occipital or temporosphenoidal lobe; in a few rare cases many abscesses have been found."

Of seven cases, the reports of which I have read, there were four multiple and three single. Two of the cases reported by Gull and Sutton were in hospital records which were not obtainable here. With the addition of my case, which was multiple, the balance would seem to be considerably in favor of the multiple variety; making five multiple to three single in eight cases. In case of multiple abscess, of course, surgical interference becomes practically useless.

I am indebted to Drs. Snyder and Thompson for the history of the case while under their care.

THE USE OF THE AQUEOUS EXTRACT OF THE SUPRARENAL GLAND IN PERSISTENT EPISTAXIS.

By LEWIS S. SOMERS, M.D.,

of Philadelphia.

ONE of the most annoying and at times serious incidents in the treatment of nasal disorders and occurring as a symptom during the course of some general diseases is the presence of continuous or intermittent nasal bleeding. In the majority of cases of epistaxis, the flow of blood is readily controlled by simple measures or ceases of itself within a short time, while in a much smaller number the bleeding is apt to be persistent and while local applications fail to modify it in the least degree, packing of the nares will apparently control the bleeding as long as the mechanical pressure is retained, but when it is removed the hemorrhage quite often starts afresh. When the bleeding comes from a definite point on the septum and resists the ordinary astringent applications, the actual cautery will almost instantly control the hemorrhage, but by this method a portion of the tissues must of necessity be destroyed and it is not unusual to have secondary hemorrhage when the eschar comes away, necessitating further applications for an indefinite period. The iron salts have probably been used more than any other remedies, but they are irritating, form a clot and are decidedly septic.

It is not my purpose to mention the long list of drugs and procedures used with varying success for the control of nasal bleeding, but to emphasize the results obtained from the suprarenal gland, especially in those cases of epistaxis extending over a long period of time,

and in which the usual gamut of procedures have been used and proved unavailing. The desiccated suprarenal gland of the sheep, being composed in great parts of animal matter, readily undergoes putrefactive changes when moistened, and in this form should not be used in the nasal cavities unless the conditions are very urgent, when it may be blown in the bleeding chamber either dry or made into a semifluid mass with water. Under any circumstances, however, when used in this form it should not remain *in situ* for more than 10 or 12 hours, or infection with local and systemic disturbances will take place.

This has previously been noted by Bates,¹ who states "that in severe nasal hemorrhage it is often difficult to reach the bleeding surface with the extract, if applied by spray or cotton on a probe, and in some cases it is necessary to syringe a 10% emulsion into the nares before the bleeding ceases. Tampons wet with the solution should not be left in the nose, because infection occurs in a few hours with vascular disturbance and secondary hemorrhage." I have not in any of my cases seen secondary hemorrhage occur from the presence of the adrenal extract in the nose, and when it does take place one cannot ascribe it to the adrenal, *per se*, but it occurs as a result of infection from putrefactive changes in the aqueous solution or desiccated powder which has been allowed to remain in the nasal cavity for too long a time. These untoward results should, however, not be considered, as they never take place if a properly prepared antiseptic solution be employed as a vehicle for the suprarenal. Unfortunately, the addition of a number of antiseptics or preservatives to the aqueous solution of the gland will seriously impair its efficiency and its maximum physiological results will not be obtained. However, by adding 1 grain of pure carbolic acid to a dram of sterile water containing 10 grains of adrenal and then filtering through paper, a solution is obtained that retains its maximum efficiency and is both sterile and permanent. I have used this formula for nearly 2 years and always find it reliable, but still more preferable is the same solution to which has been added a sufficient quantity of eucain to make a 1, 2, or 3% solution.² By this latter one attains not only the full vasoconstrictor action of the adrenal but an anesthetic action as well.

Theoretical studies of the suprarenal gland would indicate that it possessed qualifications rendering it superior as a local hemostatic and vasomotor constrictor to all other remedies, and on practical observation this is found to be the case. It has no effect on the blood itself—that is it does not produce a clot—but within a few seconds after it has been applied to the mucous membrane, blanching of the surface ensues and from its remarkable constricting action on the muscle fibers of the vascular walls, the small arterioles contract to such an extent that it is impossible for the blood to flow through them.

This may be well illustrated by the following case in which no bleeding had previously occurred, therefore differing from the class especially referred to here, but which I wish to record again as demonstrating this phase of the drug.³ The patient was a boy of 14 years, who came to my clinic with a severe attack of epistaxis, commencing but a few moments previously. The blood was freely escaping from nostrils and mouth and the patient stated that it had commenced from the left nasal chamber. Assuming that the hemorrhage was due to a rupture of the anterior artery of the septum, as is

most frequently the case, a small pledget of cotton saturated with the adrenal solution was placed over this region, as the parts could not be seen on account of the profuse flow of blood. This was allowed to remain undisturbed for a short time and then the nostril was thoroughly sprayed with the same solution and at the expiration of a few minutes the parts were cleansed with a simple alkaline solution, the flow of blood having ceased in the meanwhile. It could then be seen that all evidence of hemorrhage had disappeared and what was formerly a bleeding area was completely exsanguinated and the vessels firmly contracted, no clot remaining to later become detached and cause secondary hemorrhage.

What one may designate as chronic or persistent epistaxis is exemplified in the case reported by Lermitte⁴ of a boy, 6 years of age, who had epistaxis at almost daily intervals for two years; frequently there would be several attacks a day, some lasting for an hour or more. A long list of measures were tried on this case without the least results until by the use of local applications of the suprarenal gland the bleeding ceased and did not return.

These cases of long-continued nasal bleeding frequently assume a most unfavorable aspect, the general health of the patient becoming seriously impaired and a high grade of anemia developing. In addition to the general impoverishment of the system, the constant nasal bleeding and especially the inefficient measures used for its relief, produce alterations of the nasal mucosa, and on the slightest irritation the hemorrhage is renewed afresh.

The following case is of considerable interest both on account of the duration of the hemorrhage, the inefficiency of the usual remedies, and the prompt and permanent results obtained from the local applications of the suprarenal gland.

F. M., salesman, age 30 years, was first seen on October 26, 1899, when he stated that his nose commenced to bleed on July 1, previous. The bleeding was from the right side and there was at least one hemorrhage every day and very often this would occur two and three times daily. He would be awakened at night by the warm blood flowing down his throat, and the attacks of bleeding would last from one to four hours. A number of drugs and various measures were used, without avail. His general condition was poor, he was anemic, weak, and at times had attacks of vertigo, especially marked after the epistaxis had been profuse and excessive. There was a general hypertrophic catarrhal condition of the nasal interior and pharynx; the left side of the septum was normal while the mucous membrane over the right anterior cartilage was congested and irregular, bleeding on the slightest touch. The vessels of this portion of the nasal chamber were larger than normal, but they did not appear to be of an angiomatous character and there was no history of hemophilia or previous attacks of epistaxis. At his first visit a thin pledget of cotton was saturated with the adrenal solution and placed over the entire bleeding area of the septum, without pressure and without interfering with respiration through the affected nostril. He removed the cotton the following morning and bleeding did not recur until five days later, when he had a profuse hemorrhage at night, lasting for three hours and finally ceasing spontaneously. He was then directed to place a small piece of cotton in his nostril each evening, saturated with the solution. From this time on the adrenal was applied at infrequent intervals and the septum became pale in color, and the previously enlarged vessels were hardly perceptible. He reported at frequent intervals with no bleeding, until November 21, when the septal mucosa had entirely changed in appearance and was covered with normal epithelium, and did not bleed when touched with a probe, nor was it unduly sensitive. He has been seen at intervals during the past year, and the epistaxis

has not recurred, while his general health has decidedly improved.

Of a minor grade as to frequency, duration, and the amount of nasal bleeding, is the following case which responded admirably to the adrenal solution.

E. R., male, age 7 years, was first seen May 2, 1900. He had never had any nose or throat symptoms, nor nasal bleeding until April 25, 1900, when he had a profuse epistaxis from the right side. This took place during the night, and the week previous to when he was seen, he would have from 2 to 3 attacks daily. With but slight exceptions, there was an almost continuous flow of blood from the nose for 1 week. At times it would only be a few drops, but more frequently, a steady stream would flow from the nostrils. His general health was good, except for the anemia already present from the loss of blood, and the rhinopharynx was normal, except the anterior cartilaginous portion of the septum, which was red and granular, the vessels dilated and bleeding on the slightest touch. The blood appeared to ooze from all parts of this portion of the septum, and did not come from any large vessel. Adrenal was applied on cotton as in the previous case, other methods having been used without avail, and his mother was instructed to drop several minims of the adrenal solution into the affected nostril twice daily. This was discontinued in a few days, and the bleeding has not recurred, while the affected tissues are pale in color, perfectly smooth, and can be handled with considerable roughness without the least evidence of bleeding.

When the suprarenal gland is used in these cases and in any nasal pathological condition characterized by congestion and erosion of the mucous lining, the results obtained clearly indicate that it possesses a still further action than that of vascular constriction, and this is shown by the rapid changes taking place in the physical condition of the parts. The erosions heal and a general nutritive tone is given to the tissues that no other local remedy seems to possess. This has been noticed in all my cases in which the nasal conditions indicating its use were present and, therefore, in addition to the drug being the most remarkable vasomotor constrictor that we possess, it is also of great value for its local nutritional effects, and its power of acting as a pure muscle tonic.

THE BIO-CHEMICAL BASIS OF PATHOLOGY.

By HENRY A. BUNKER, M.D.,

of Brooklyn, N. Y.

At the meeting of the Hospital Graduates' Club, held May 27, 1898, I had the honor to present a paper bearing the above title, in which paper were embodied certain results obtained in laboratory work in the field of biological chemistry, together with some deductions as applied to pathological conditions. In that paper the hope was expressed that the outcome of researches then under way might warrant the early presentation of a further paper under the same title, which would substantiate the correctness of these deductions. That there have been many disappointments, with apparently meager reward for much hard work, may go without the saying for those of my fellow-members who may have essayed investigations in this exacting field in conjunction with general medical practice. A profound faith in the future of this comparatively new

field of research is offered as sufficient justification for presenting this paper.

Until within the past few years our knowledge of pathological conditions has been limited to macroscopical and microscopical findings. While such knowledge is essential—in fact, further progress would be impossible without it—and too high praise cannot be awarded to the workers in that field, it may be safely stated that, except in the working out of disputed and, in the main, minor details, morphology has practically reached its limit in the field of research. We must go back of structure and form in order to determine the causes for the now well-recognized variations in detail.

If we accept the time-honored teaching that all pathological processes, whether those involved in tissue structure or in the modifications in composition and character of the body-fluids, are originally only deviations from normal physiological routine, we are obliged to conclude that the real secrets of disease-action must be sought back of and precedent to histological and morphological change. In other words, nutritional disturbances and perversions must antedate change of structure from the normal.

Therefore we must look to the cell as the starting point of pathological deviations just as we must consider it the beginning of physiological life, for in so far as the cell is perfect in activity and function, just so far is the organ, which is only a colony of similar cells, perfect. The activity of the cell, its very existence as a cell, is inherent in the nucleus, the surrounding cell-protoplasm being apparently a nutritional and functional envelope.

As a general proposition it may be stated that any normal cell nucleus resembles in every respect, morphologically and, so far as at present determined, also chemically, all other normal cell nuclei. According to Weisman and others, the amount of chromatin substance in every active cell among the millions of cells throughout the body is the same as in the primitive cell from which the organism sprang; and further, that in any given species, even the same number of chromatin filaments persists throughout, under whatever changed conditions normal cell proliferation takes place.

From the nuclei of the cells then are formed new nuclei for other and similar cells and from the cell-protoplasm are constructed, by the bio-chemical activity of the nuclei, the varied connective tissues as reticula, bone, cartilage, etc., etc. In this process in its entirety, whether observed in the life history of unicellular organisms, or in the complex structure of more highly evolved forms of life, we recognize living matter whose vital characteristics as opposed to matter not living are, according to Huxley's classical definition, first: "universal disintegration by oxidation and its reintegration by intussusception of new matter, giving rise to the varied forms of growth and repair, and second: the universal tendency to cyclic change or reproduction."

It is apparently in this conception of cell and tissue growth that the secret of normal and abnormal action must be sought, for the whole problem would seem to revolve around the perfection of the process of oxidation of waste and of the preparation of new matter for reintegration and reproduction. If there is no distinguishable difference in the active centers, the nuclei of the cells, we must look to the distinctive characteristics of the varied forms of new material built up by their activity out of the cell-protoplasm—the intercellular

connective tissues being considered simply as cement substance or as stroma—to furnish the clue to the character of the vital processes by which they are produced.

Under the law known as the physiological division of labor then, we find that the life-energy, as embodied in the primitive cell and which insures the persistence of all living things, is broken up into the different manifestations of that energy which marks the wide distinction between the primitive cell and the complete physical organism. Under the action of this law, connective tissues are found to vary so widely in the different organs and structures of the body, both in character and form, that we are obliged to assume the existence of a selective affinity on the part of the active nuclei for the various elements of nutrition required; for all the nutritive material needed for growth and function is contained in the fluids in which the cells, organs and tissues are constantly bathed.

Now simple protoplasm, as such, cannot continue as living matter, if deprived of the nuclear substance which gives it life; it would seem to be simply an intermediate material, or, perhaps, rather a transition state of organic matter between the active, directing and selective nucleus and the connective tissues which determine form and function. In other words, the character of an organ or tissue differs from that of other organs and tissues by virtue of the ability of the cell-nuclei to pick out from the tissue fluids holding it in solution the material which will build into the structure required.

As the composition of the blood-plasma throughout the body varies slightly, if at all, and as the specialized character of organic structure varies within wide limits in continuous and contiguous tissues, as in bone and ligament, muscle and aponeurosis, etc., it must follow that not only are all the elements of nutrition contained in solution in the tissue-fluids derived from the blood-plasma, but that the cell-nuclei of each tissue are possessed of the power of appropriating just what is wanted and nothing more. Any solution, therefore, of the problems involved in the processes of growth, waste, and repair, must rest primarily upon: (1) the quality of building material required and the method or methods of rendering it suitable for the purpose; (2) the character of structure to be built; and (3) efficient means of rendering innocuous, utilizing, or otherwise disposing of, waste-products.

It is a fairly proven proposition in biology that the living cell is enabled to prepare material for its own nutrition, by means of a secretion or emanation from its own substance, of special enzymes which seem to act universally by a process of hydrolysis; by simplifying and splitting up—by the introduction into its chemical formula of the elements of water—complex material, so that the subsequent synthesis which appears to be the distinctive function of protoplasm, may be possible. In all forms of cell and microorganic life, this fact seems to be fairly well established, although thus far efforts to isolate and identify such enzymes have met with but partial success.

That such enzymes do exist, however, is shown in the production of peptones and their concomitants in bacterial decomposition of proteids, in the glycolytic and emulsion forming powers of cells and other microorganisms on carbohydrates and fats and in all fermentations.

If we study, for example, the life history of the yeast

cell as a type of micro-organic life, many interesting facts may be noted. This cell secretes within its own substance and throws off, something which passes into solution in the surrounding culture medium, or even in water, which possesses the power of hydrating and splitting up carbohydrates previous to assimilating them to its own needs of protoplasmic growth. Now, yeast cells contain nitrogenous matter as proteid, carbohydrate as glycogen and cellulose, fat and mineral matter. In the classical experiment of Pasteur, it is demonstrated that a culture medium composed of sugar, tartrate of ammonia and the ash of other yeast cells furnishes a sufficient pabulum for the continued and extensive growth of new cells, although neither proteid substance nor fat are contained in the solution and the carbohydrate supplied as sugar is of a much higher degree of hydration than that built in as glycogen and cellulose. It is known further, that preparatory to the synthetic dehydration by which it is built into living matter, the sugar in this solution undergoes a radical change in its optical properties and therefore in its molecular structure. This inversion or division, which as far as my investigations have led me, seems to take place in the nutrition of all living cells, not only in carbohydrates but in all their derivatives, is a fact of such far-reaching importance that I here venture to suggest, by way of digression, that upon it will be found to hinge some of the deepest problems in biology, pathology, immunity and possibly also, heredity. There is no evidence of any such change taking place in the other constituents of Pasteur's artificial culture medium for yeast. The nitrogen of the tartrate and the mineral matter of the ash seem to enter into organic combination without material change, the synthesis producing proteid in its union with one half of the carbohydrate cleavage, while the other half is deposited as cellulose and glycogen, the alcohol produced being apparently an accumulation product and, on account of its symmetrical molecular structure, contributed equally by each moiety.

The life history then, of the yeast cell, whether grown in what may be considered its natural environment or in one artificially provided, is, first: preparatory hydrolysis and inversion by means of which the nutritional supply may be built into proteid already existing; by, second: successive dehydrations and syntheses—the formation of fat being apparently intermediary; third: the building up out of the carbohydrate thus incorporated into proteid, of cellulose as tissue structure, and, fourth: the storage of unused carbohydrate for future necessity, as glycogen. The entire process of synthesis is followed by, or, as is more likely, accompanied at each step by, disintegration through a reverse order of sequence—fat being again intermediary—to the close of the reproductive cycle. As the evolution of the heat of vital activity is continuous throughout, there must be an equally progressive oxidation of the waste of each stage to the final oxidation into carbon dioxide and water.

A point of considerable importance in the subsequent consideration of the subject of this paper, is the fact that only under anaerobic conditions do yeast cells produce any appreciable amount of surplus alcohol. If, as suggested above, alcohol is an accumulation product of ferment action—and it acts as do all such accumulation products, by finally destroying its producing ferment—we may comprehend how, in the presence of the free oxygen of the atmospheric air, the more vigorous

growth and multiplication of the organism compels an equally rapid oxidation to aldehyde. This aldehyde is the soluble carbohydrate needed for reintegration as proteid in the formation of new cells. The invariable presence of succinic acid in sugar fermentation and also of the compound ethers under special conditions, give some weight to this theory as to the origin of an alcohol surplus. This outline of the life history of the yeast cell may be taken as the type of all cell life, in so far as biology is unable to prove to the contrary.

As in the yeast cell, so in all organic life, there is abundant reason for believing that none of the food-stuffs are laid down in the body as such, but that their appearance as body stuffs is possible only by a process of synthesis into the proteid of the cell, for analysis fails to show that fat, for instance, is ever formed in the body except as a disintegration product of proteid. This is certainly true of the albuminous bodies, for it is a notable fact that no nitrogen or nitrogen-bearing body is stored up as reserve in the body, but that, on the contrary, such material immediately becomes part of the active bioplasm and as such is at once used up by the increased activity it stimulates, so that within a few hours after its ingestion a corresponding amount of nitrogen is practically wholly eliminated as urea.

It is far different, however, with the fats and carbohydrates. Here is undoubted storage of what is not required for immediate use, for future consumption, to be drawn upon as may be demanded and converted, the one into the other, according to the exigencies of vital activity.

The fact that in experiments upon animals the elimination of urea which is the measure of the extent of proteid metabolism, does not show a uniform decrease during starvation, would certainly indicate that, in the absence of the direct incitement to increased metabolism brought about by ingestion of nitrogen, the source of supply for heat production is a stable one. In accord with this is the further fact that the ultimate fate of fat in the body is to become oxidized through a regular sequence, to carbon dioxide and water with the production of heat and energy, whether physical or molecular; that the process is a continuous one and that the seat of this oxidation is throughout living proteid substance.

The gradual disappearance during starvation of glycogen from the liver and muscle—muscles showing its presence much later than the liver—the acceleration of its disappearance by muscular work; the small amount of dextrose found in muscle during life and its rapid increase after death,² together with the equally rapid decrease of glycogen and the appearance of dextrin as an intermediate product, are all in full accord with the view that the transformation of waste is only through the medium of repair and that this takes place only through the production of proteid substance.

In laboratory experiments on mice, by injecting solutions of methylene-blue and of indigo carmine under the skin, and killing the mice as soon as color showed in the urine, I found that the cell-protoplasm of the excretory glands especially had taken up the stain. The stain had not been deposited in the connective tissues and, if the mouse was not killed promptly, the color was found to have wholly or partially disappeared according to the time after injection. While admitting that the results of these experiments are not altogether conclusive, they are respectfully submitted as furnishing a link at least, in the chain of evidence that the

entire process of metabolism takes place through the formation of proteid.

That fat and tissue carbohydrate are mutually transformable through the medium of proteid production would seem to be strongly indicated by many facts, among which may be noted the large amount of fat together with the small amount of carbohydrate—none of the latter as glycogen, so far as I am able to find—as found in the egg; while in the embryo the converse is true. In the embryo there is an enormous amount of glycogen to supply the rapidly growing tissues and to insure during early infancy a sufficient formation of fat to act as a reserve from which may be drawn the material for future growth.

On the other hand, the inhabitants of the arctic regions and the carnivora, from whose diet carbohydrate—except the small amount obtainable from proteids by digestive cleavage—is wholly excluded, do not lack the muscular development inseparable from glycogenic activity either as embryos, infants or adults.

Finally, in breaking down proteid material, whether by means of digestive enzymes or by chemical hydrolytic agents, we always find split off carbohydrate as a glucose, or rather as an aldehyde or a ketone, whose power of reducing copper oxide³ varies apparently with the degree of dehydration which has taken place in its synthesis. That these cleavage carbohydrates are in every case aldehydes or ketones may be easily demonstrated by the usual tests for these bodies. I am most familiar with the ammoniated silver nitrate solution of Tollens, from which the metallic silver is deposited as a mirror on the glass of the test tube, in the presence of an aldehyde. I have done little with the ketones except a slight study of their phenylhydrazones. That the aldehydes at least undergo varying degrees of dehydration in proteid synthesis, the degree depending apparently upon the tissue from which they are split off, is shown by their different and characteristic osazone crystallizations with phenylhydrazine, as well as by their varying power of reducing copper oxide referred to above.

While the carbohydrate product of digestive proteolysis is always an aldehyde or a ketone, the fat that is also found in the residue has been considerably modified in character and, aside from the strictly interstitial fat—which is still storage fat—is never the so-called neutral fat which serves as reserve.

Thus Dormeyer⁴ finds "that after muscle has been subjected to preliminary gastric digestion, ether extracts 8.5% more of the total fat obtainable; and that without such preliminary digestion, extraction with ether is useless for quantitative purposes." E. Bogdanow believes that "the fat which is thus soluble in ether with difficulty, is a real constituent of muscle plasma and states that it is richer in volatile fatty acids than that from the surrounding connective tissues."

It would seem, therefore, that these volatile fatty acids are not produced by proteolytic action. They are apparently acids which have not as yet been built into proteid, for the acids derived from the breaking down of strictly albuminous material are always found in combination with an amidogen group, sometimes two or more, and vary in proportion with special tissues. It might even be said that the character of tissue may be determined by the proportions of these amido acids relatively to each other, so characteristic does this proportion seem to be. For instance, the predominant amido acid of gelatine and its mother substance collagen

is amidoacetic acid, glycocoll, although with it are found amidopyrotartaric acid, amidosuccinic acid and leucine but no tyrosine, both amido compounds. The only other connective tissue substance in which glycocoll has been found is elastin, but here there is, according to Drechsel, no accompanying amidosuccinic acid or amidopyrotartaric acid, but a small amount of tyrosine. Lysatinine,⁶ but no lysine, both diamidoacids were also found. So also, Siegfried⁶ found amidovalerianic acid in reticulín from reticular tissue and from no other, not even from white fibrous connective tissue with which reticular tissue is "anatomically continuous and histologically identical." Amidopyrotartaric acid which is found in elastin and gelatin is not found in reticulín. And so on with all the tissues which have thus far been studied.

It is noteworthy that the so-called antipeptone which is the end product of proteolytic digestion opposed to the group of amidoacids which constitutes the hemi-, or more acid half of the proteid decomposition, is now found by Siegfried⁷ to be an amido-, or perhaps rather a multiple amidoacid which he calls carnic acid and which is capable of being further split up into lysine and lysatinine. Without wearying you further, sufficient has been said, I am sure, to indicate the rather strong probability that the particular character of structure may be dependent upon the predominant amidated or nitrogenized fatty acid or group of fatty acids which so evidently go to build it up.

Now the question arises as to the origin of these acids. In view of the fact that the neutral or storage fat of each animal species is characteristic, regardless of the form of the fat taken as food, or where fat forms no part of the diet, that is, that pork fat is always lard and beef fat is always tallow—differing only in the percentage of the different fatty acids combined with glycerine—the indication is rather strong that fat has its origin in the synthetic activity of protoplasm. The only experimental proof of this, so far as I am aware, is that of Munk, who showed that free fatty acids fed to animals, are synthesized into and deposited as reserve like the neutral fats normal to the animals experimented on.

The fact that the higher fatty acids are easily oxidized in the laboratory into acids of lower carbon content; the fact that aldehyde and ketones, the carbohydrate factors in tissue construction, are direct oxidation products of primary and secondary alcohols, becoming corresponding acids through further oxidation, and finally, the fact that the oxidation processes of the body must be continuous, all would seem to make the relation of these acids to the food carbohydrates a fairly clear one. We read and talk of the system of drawing on the reserve of storage fat, but very little is known of the methods by which such stored material is prepared to enter the circulation or to become part of the tissue fluids. It is known that the neutral fats are not and can not be absorbed as such. They are decomposed for absorption, but are at once reintegrated, by the agency of the lymphoid cells of the intestinal villi⁸ preparatory to being laid down as reserve. Investigation suggests that perhaps the manner in which such storage takes place may furnish the clew to the methods by which the fats are utilized.

Such high authority as Hammarsten,⁹ while admitting that fatty tissues supply a "depot where there is stored during proper alimentation, a substance of great importance in the development of heat and vital force,

which on insufficient nutrition is given off as needed," has no explanation to offer for this fact further than that "the fatty tissues, on account of their low conducting power, become of great importance in regulating the loss of heat from the body. They also serve to fill cavities and act as a protection and support to certain internal organs." While there is no doubt of the correctness of these statements, such functions of the fatty tissues must be considered as purely subsidiary.

The real importance of the general plan of this physiological storage would seem to lie in the fact that the organs so supported and protected are organs of intense and unceasing activity, requiring for their energy incessant and heavy drafts upon a convenient and stable source of supply.

Between the mass of fat surrounding or lying adjacent to such organ or lymphatic, or other gland and the organ or gland itself, there is a fine network of lymphatic vessels. Now lymphoid cells are notably active in all the processes of anabolism and, in accordance with the general proposition that all metabolism is an alternate process of breaking down and building up, it would not be a violent assumption to suppose that these cells bring about just such chemical changes in this stored fat as would be necessary to form the various tissue fluids qualified to meet the specific demands of the tissues to be supplied or nourished.

In other words, given the base or bases of lysatinine, lysin, or antipeptone—one or more of which being apparently always present in all forms of proteid substances—special character of tissue would depend upon the particular fatty acid to which they, as bases, are united. As the only source of such acids is the neutral storage fat, their presence as acids, must depend upon the degree of hydrolysis to which the neutral fat is subjected in the preparation for organic or cellular assimilation. With this idea in view, I endeavored a few years ago, to demonstrate the existence of a fat-splitting enzyme in bronchial glands, but in view of the elusive nature of enzymes in general and the limited acquirements of the experimenter, it will not surprise you to learn that the several attempts were wholly futile. The frequent appearance, however, as observed with the microscope, of fatty acid crystals in fat cells—particularly in those cells lying in closest contact with the lymphatic network referred to, and also in the lymph-spaces of the organs themselves, gives hope that the future will provide a more fortunate investigator.

If the hypothesis here presented be true, as to the origin of tissue differentiation, for all tissues are supplied with lymphatic vessels and glands and also with interstitial spaces filled with tissue fluids, we need not feel obliged to accept without reservation, Waller's assumption of an "interorganic relation" under which "the waste of one organ serves as the raw material for another," for each organ and tissue is seen to supply a complete metabolism by and for itself and pathological change would simply be the result of deviations in degree or sequence of anabolism and catabolism in relation to each other.

Thus, an excessive accumulation through too active formation, or through imperfect oxidation and elimination of any of these organic acids would lead to hyperplasias—the special type depending upon the particular acid involved,—their perversion to metaplasias, etc., etc.

The waste or oxidation products of each tissue or organ need not, therefore, be the end products of met-

abolism of the body as a whole—carbon dioxide, water and urea—although to a certain extent this is really the case, but would certainly be the antecedents of these and whose retention would give rise to such toxic conditions as the acid diathesis, such as gout, rheumatisms, etc., on the one hand, and to uremia and uremic conditions on the other. The ready production by Drechsel and others of urea, by various hydrations and oxidations of the different basic substances derivable from proteids, together with the fact that in birds and reptiles the nitrogenous end product of physiological waste is uric acid and not urea, furnish a logical reason for this assumption.

The different forms of physiological and pathological degeneration would seem to point to imperfect hydrolysis, due either to impaired or perverted enzyme action and subsequent faulty dehydration and synthesis, or to imperfect synthesis of properly prepared material. In fatty degeneration, for instance, the cells seem to have lost the power of completing the proteid anabolism from carbohydrate and the process stops at the fat stage. The cell then loses its protoplasm through ordinary vital waste and deposits the fat instead of new protoplasm. This deposited fat, not having reached the stage of organic combination where it can be oxidized with physiological rapidity, gradually accumulates to the final destruction of the cell as such. In myxedema and in the amyloid, hyalin and colloid types of degeneration, it would seem that the stops occur at the different stages of normal cell activity, with the result that in each case, otherwise normal material fails of complete metamorphosis and is deposited in the tissues. In glycosuria, however, the excess of glucose, on account of its solubility, is carried off in the body fluids and is eliminated as such.

However this may be, the products of cytoplasmic degeneration seem always to be normal physiological substances, their excess, location and environment making them pathological, proving Huxley's definition of dirt as "matter out of place" to be true physiologically as well as physically.

To return to the amido acids. We never find them combined with glycerin as the free acids themselves. It would seem from this, in view of the abundance of glycerin in the body-fats and the fact that it is never found in the free state, that at the instant of the union of the acids of the fat with the amidogen, the glycerin is at once set free as triatomic alcohol and as promptly disposed of according to the demands of normal metabolism. At any rate it disappears immediately it is broken off from its combination with the fatty acids, apparently either by (a) union with whatever free acid may be available to serve again as storage fat, or under pathological conditions to become degenerative fat; or (b) by oxidation to aldehydes and ketones, for the formation of new proteid, physiologically or pathologically, to pass off as glucose through failure of normal synthesis, or (c) by oxidation to a succession of acids whose physiological or pathological character depends upon the orderly sequence and completeness of the oxidation processes.

These acids cannot exist normally in the body in a free state any more than can the glycerin from which they are derived. Their appearance implies at least a partial failure of metabolism. Such failure gives rise to retention acid toxemias either as the acid diatheses before referred to, or to autotoxic states not so well recognized, such as diabetic coma, due, as now be-

lieved, to the presence in the body fluids of B-oxybutyric acid.

The physiological disappearance of glycerin by oxidation to aldehyde for the formation of new proteid, as just suggested, is rendered extremely probable by the fact before noted that aldehyde is always a cleavage product of proteid decomposition and by the further fact that inseparable from aldehyde as a result of such cleavage, are the amido acids.

Like glycerin and its derivatives, the fatty acids, the amido acids are never found free under normal conditions. They are the normal body acids united to one or more amidogen groups, NH_2 . This union is of such an intimate character that prolonged boiling in caustic alkalies does not destroy it and under normal conditions, although the acid half of the amido compound is successively oxidized to acids of progressively decreasing carbon content, the amidogen appears to maintain its relation with each succeeding acid to its final elimination in combination with carbonic acid as urea, carbamid.

The fact of the continuity of the amidogen or nitrogenous half of the different amido acids would indicate the importance of the grouping and gives strong confirmation of the assumption of Waller before referred to "that the waste" (meaning the oxidation acids only) "of one organ serves as the raw material of another." In no other sense may the amido acids be considered as waste material, and then only as they occupy positions lower in their series through successive oxidations of the acid radical.

The invariable presence of amido compounds—notably the monamids of aspartic and glutamic acids in germinating plants¹⁰ and of aspartic and glutamic acids, both amido acids, in the nutrient material of animal embryos, can mean only that they are necessary for proteid construction. Hlaziwetz and Haberman¹¹ have found as much as 23.8% of aspartic acid in egg-white.

If the amido acids higher in the series are of such importance in the normal physiological fibrosis which takes place in forming the embryo and are such important factors in maintaining the specialized character of the different body tissues, as heretofore cited, why, it may be asked, should they not be of equal importance in the formation of new tissues and cicatrizations in Nature's attempts at repair after degenerations and injuries? For instance, we know that all cures of the pulmonary lesions produced by tuberculosis are by fibrosis. I have found that the apparently predominant acid in this fibrosis is the amido-succinic acid; but whether it is the most important, I am not yet prepared to say. Its presence is, I believe, invariable.

This conclusion, which I have maintained for the past four years, has recently received grateful confirmation in a paper by Dr. Jonathan Wright,¹² of this city. I take the liberty of abstracting from his paper a quotation from an article by Viquerat, in *Centralb. f. Bakt.*: "Tuberculin, glycerin extract, TO or TR is nothing but a watery solution of an alkaline succinic acid salt, . . . Further researches, which will soon be published, show that succinic acid plays the principal part in the tuberculosis question; the tubercle bacillus, or rather the succinic acid bacillus, does not form a toxin and works in this connection much more as the producer of a diathesis like gout than as a true toxin-forming variety of bacillus."

The result of the further researches of Viquerat, the early publication of which is promised, will doubtless

be found to be extremely interesting. I do not know the extent of his researches into the physical properties of tuberculin extract, but I venture the prediction, based upon my own investigations, that here again, as suggested in the early part of this paper, the spatial arrangement of the atoms in the molecular structure will be found to be of the utmost importance. I am sorry to say that I have nothing sufficiently definite to offer upon this point now. Unfortunately my notes are too incomplete to justify any conclusions bearing upon this problem as relating to specific biological and pathological conditions, but enough has been learned to show conclusively in what direction the distinction between living and not-living matter lies.

This distinction which indicates infallibly the direction of the forces which tend to reintegration on the one hand and to disintegration on the other, is so fundamental that it is shown in the earliest and most primitive forms of life and is seen to persist throughout to the final dissolution of organic substance into its primary elements. What may be the nature of this form of energy it is impossible to say; as in other forms of force, we may never progress further than recognition of them by their effect upon matter. At present we are obliged to conclude with Pasteur:¹⁸ "Is it not necessary and sufficient to admit that at the moment of the elaboration of the primary principles in the vegetable organism, an asymmetric force is present? . . . Do these asymmetric actions, possibly placed under cosmic influences, reside in light, in electricity, in magnetism or on heat? Can they be related to the motion of the earth, or to the electric currents by which physicists explain the terrestrial magnetic poles? It is not even possible at the present time to express the slightest conjecture in this direction.

"But I regard as necessary the conclusion that asymmetric forces exist at the moment of the elaboration of natural organic products; forces which would be absent or ineffectual, in the reactions of our laboratories either on account of the violent course of these phenomena, or because of some other unknown circumstance."

Whether we accept the theories of Pasteur or those of Le Bel and van't Hoff, we must recognize this force or these forces as a profound modifier of chemical affinities as manifested in laboratory reactions, for the whole of biological chemistry is not told when these reactions are noted.

The profound and far reaching bio-chemical transformations which are seen to occur in the processes of assimilation and also of disintegration under the influences of normal and abnormal cell activity are brought about by the collective and harmonious action of the individual cells of each gland or organ. That this force is the determining factor in the bio-chemical reactions which take place within the cell, is evident from the uniformity of the results obtained. Under physiological conditions, lines of cleavage, synthetic rearrangements and successive series of oxidations are seen not to vary, but to follow a well defined and symmetrical sequence, disturbance of which is followed by a more or less widely distorted condition of affairs which we recognize as pathological.

If we consider the probable size of the proteid molecule, we must realize that the possible lines of cleavage and transformation are many. If after normal cleavage, an imperfect oxidation takes place, or complete oxidation follows an imperfect cleavage, or imperfect cleavage and imperfect oxidation coexist, we see that the

possible modifications of metabolism must be almost infinite. It is in these modifications and perversions of normal bio-chemical relations—those of physiological sequence—that the cause of morphological change must be sought; and it is upon the recognition and understanding of the chemistry and molecular physics involved in tissue structure and in tissue maintenance, that the pathology and therapeutics of the future must be based.

CULTIVATION OF THE ASPERGILLUS IN URINE.

By L. NAPOLEON BOSTON, M.D.,

Bacteriologist to the Philadelphia Hospital and to the Ayer Clinical Laboratory of the Pennsylvania Hospital; Demonstrator in charge of Clinical Laboratory, Medico-Chirurgical College.

(Contributed from Laboratory of the Philadelphia Hospital.)

THE frequency with which one detects the presence of yeast and mycelium in the urine voided by the inmates of this institution prompted me to investigate the apparent relation existing between these and other fungi, which are in many respects similar. For this purpose the *aspergillus fumigatus* and the *aspergillus nigr*a were cultivated on urine as follows: Acid, alkaline, and acid diabetic urines were placed in culture tubes, in quantities of 10 to 15 c.c. each. Where the urine was found to contain albumin, it was heated sufficiently to precipitate this body, after which it was filtered and placed in tubes, as above stated. One-half of all the tubes was placed in a temperature of 212° F. for 45 minutes. Tubes prepared in this manner were inoculated with the *A. fumigatus*, care being taken to introduce, as nearly as possible, the same quantity of the growth at each inoculation; always cultivating the organism on acid, alkaline, and acid diabetic urines. To accomplish this, 6 tubes, 2 of each variety—1 of which was sterile—were employed. The same precautions were observed in the study of the *A. nigr*a. All inoculations were made April 13, 1900, and the following is a record of the changes observed—cultures examined daily to May 13, 1900.

SERIES NO. 1.—*A. FUMIGATUS*.

Sterile acid urine, kept at room-temperature, 4 days after inoculation, presented a surface-growth which was easily broken by shaking the tube. Microscopic study detected clumps of mycelium. Many spores were found arranged in large clusters. Mycelial threads crossing one another were also observed. On the sixth day the urine was alkaline, of an amber color, and showed a heavy precipitate.

Acid urine (not sterilized) was rendered alkaline in 4 days—possibly due to bacteria. Growth less pronounced than on sterile urine. Microscopically, this growth appeared to be composed of amorphous material and spores. Color, amber.

Sterile alkaline urine presented a less pronounced growth than did acid urine. On the slightest agitation this growth

sinks to the bottom of the tube. Alkalinity was increased on the sixth day. The slight surface-growth contained only few spores, while the color was slightly deepened. On the twenty third day the surface and upper one fourth of the urine were of a chocolate color, and by the thirtieth day this color had extended to the bottom of the tube. The sediment and surface-growth at this time contained only few spores. To insure against the possibility of contamination, cultures were

FIG. 1.—*Aspergillus fumigatus* from acid diabetic urine. Objective (Queen) $\frac{1}{2}$. Eye-piece iv.

made from this tube, and were alike in giving negative results.

Alkaline urine (not sterilized) presented a more marked growth, which was found to be largely composed of spores. Alkalinity was not increased until the tenth day, when a browning was observed at the surface of the liquid, which increased gradually to the sixteenth day, when the entire urine was of a brownish-black color.

Sterile acid diabetic urine presented a whitish growth in 48 hours, covering the surface of the liquid; and on the fourth day tipping and shaking of the tube did not displace

FIG. 2.—*Penicillium glaucum* from potato culture. Objective (Queen) $\frac{1}{2}$. Eye-piece iv.

the urine, and the growth was beginning to acquire a greenish hue, while the urine remained of an amber color. Microscopic study detected many mycelial threads, each displaying its individual sporangium at one extremity, and few spores—the usual findings when *A. fumigatus* is cultivated on potato or bread-paste. On the ninth day the growth was thickened, wrinkled, and separated from the side of the tube, while its surface was studded with sporangia.

There was practically no difference in the reaction of the *A. fumigatus* when grown on unsterilized diabetic urine.

SERIES NO. 2.—*A. NIGRA*.

Sterile acid urine showed a marked white surface-growth on the fourth day, which prevented the urine from changing its position when the tube was inclined. This growth was composed of mycelial threads and many spores. Reaction neutral. Color unchanged.

Acid urine presented both a surface-growth and a heavy sediment. The surface-growth was composed of mycelial threads and spores. Reaction, alkaline. Color unchanged. No further changes were observed.

Sterile alkaline urine presented but slight surface-growth on the fourth day, and by the seventh day this growth had sunken to the bottom of the tube. This growth was found to be composed of granular material, and few spores, which presented the usual dark color. Reaction neutral, after the fourth day, and at the surface of the liquid a slight reddening was noticed, which increased to a deep cherry-red.

Alkaline urine (not sterilized) differed only in that it was rendered highly alkaline, and at the thirtieth day the upper half of the liquid was changed to a dark brown.

Acid diabetic urine presented the same changes noted in the study of the *A. fumigatus*, except that the culture-medium acquired a dull black color, which was first observed at the surface and spread rapidly, discoloring the urine.

A review of the literature on Aspergillosis, made by T. A. Rothwell, of Manchester, England, credits Rénon¹

PLATE 3.—Mycelial threads (*aspergillus nigra*) from acid urine as shown by both $\frac{1}{2}$ and $\frac{1}{4}$ lenses, B. and L.

as the first to call attention to the presence of mycelial threads and spores of this fungus in the urine of animals suffering from experimental aspergillosis (pseudo-tuberculosis). This author found that in from 24 to 48 hours after inoculation, he was able to cultivate the *A. fumigatus* from the animal's urine, and in most instances he found mycelium—these findings being more constant as the disease progressed. At autopsy these animals were found to present classical lesions of the bladder and kidneys. Rénon attributed these findings to infection through the venous blood supply, as his attempts to cultivate the aspergillus on urine proved that it had little tendency to vegetate when kept at incubating temperature.

Many writers have called attention to the fact that the aspergillus and other fungi develop best on acid medium, at a low temperature; and the same has proven true in my study of the organism on urine, which probably explains the wide difference between the findings of Rénon and those of the writer. My review of the literature has been rather hastily accomplished and possibly some records have escaped my notice. However, I have been unable to find any special record of the effect of this organism on human urine.

A NEW BLOOD-STAIN.

By RANDLE C. ROSENBERGER, M.D.,

of Philadelphia.

Demonstrator of Bacteriology and Morbid Anatomy in Jefferson Medical College.

(From the Laboratories of the Jefferson Medical College Hospital.)

EVERY year, or perhaps more frequently, some one publishes a new blood-stain.

One of the latest stains is that made according to the formula of Jenner, the only objection being its tedious procedure and uncertain outcome. After it is once made correctly, it keeps indefinitely and stains very well. Ehrlich's triacid, Ehrlich's triple-stain, Ehrlich-Biondi-Heidenhain stain—these all have their advantages, yet who has not had his failures with these stains to probably far outnumber his successes. The precipitation of the stains upon coverglass preparations is also a great disadvantage, the trouble being that in some formulae filtering is recommended and in others not.

Plehn's and Prince's stains are also very good ones, both for the malarial parasite and for the leukocytes. These are also, among many, easy to prepare. So many blood-stains deteriorate in a couple of weeks or sometimes less, that when you wish to use them you find they have spoiled. It stands to reason that a freshly prepared stain stains best, but when in a laboratory a couple of hundred students have to be supplied, then a stain easily prepared and easily kept for a couple of months is the one to be used. While performing Bremer's tests with anilin dyes upon diabetic blood—phloxin, congo-red, benzo purpurin, and methyl-blue—I was tempted to place them under the scope. Phloxin showed the granules of the leukocytes beautifully, and I then determined to prepare a blood-stain in combination with a basic dye.

In trying to perfect the stain, discouragements were repeatedly encountered, and at some critical moment hopes were always blasted. Methylene-blue being one of the best and most uniform stains, I tried this in combination with the phloxin. Saturated aqueous solutions of both these stains were made and the formula which has worked the best is as follows :

Saturated aqueous solution of methylene-blue.....	50 c.c.
“ “ “ of phloxin	20 c.c.
Alcohol (95%)	30 c.c.
Water (distilled).....	60 c.c.

These are all mixed indiscriminately together and a bluish solution is the result.

A precipitate generally forms and the stain needs "shaking before using." The blood-films can either be fixed by heat (115° to 120° C. for 20 minutes) or in equal parts of alcohol and ether, or absolute alcohol. The stain works well in either case of fixation. After the preparation is dried from alcohol and ether, or from alcohol alone, the stain is applied and allowed to remain from 1 to 3 or 4 minutes, washed freely in water, dried and mounted in balsam. As in all other blood-stains the nucleus of the white cell stains either a deep or light blue, according to its variety; the red cells a pinkish color or a reddish green. In the finely granular oxyphiles, the nuclei take the stain quite darkly, the granules either a dull pinkish color, or a bright red, denoting that they are slightly acidophilic and not always neutrophilic. The nuclei of the lymphocytes take the stain deeply, and around their periphery

numerous basic granules are demonstrable as a rule, while some do not show granules.

In the coarsely granular oxyphiles the nucleus takes a light blue stain, the granules are bright red, almost brilliant.

The myelocytes take a very faint blue stain, the nucleus taking up nearly the whole cell, while in some, small granules exhibiting a slightly acidophilic reaction are seen, while in others no granules are demonstrable. These cells are, of course, not found in normal blood, but in splenomedullary leukemia especially. The hyaline cell, which according to some is identical with the large lymphocyte, takes a uniformly light blue stain and no granules as a rule are demonstrable; occasionally, however, a few basophilic granules may be present. Finely and coarsely granular basophiles take a deep blue stain, the nucleus and granules both exhibiting an affinity for the basic dye.

The red corpuscles in normal blood generally take a pinkish stain, while in pernicious anemia and leukemia they take a reddish green or a yellowish with a faint tinge of pink.

The nucleus of the normoblast takes the basic stain.

Not only is this stain useful for blood-cells, but it is also a fairly good one for the malarial parasite of any variety. The estivoautumnal and the quartan parasite stain especially well; in any variety it stains a bluish-green, while pigment granules show up very decidedly upon this background.

A Case of Spontaneous Hemorrhage from the Iris and Ciliary Body Into the Anterior Chamber Due to Splenomedullary Leukemia.—Fr. Sorger (*Munch. med. Woch.*, Jahrg. 45, No. 35) reports a case of hyphema occurring in a patient who had splenomedullary leukemia for 6 months. Upon examination there was a hyphema divided into 3 layers. As spontaneous absorption did not take place under medicinal treatment, paracentesis of the anterior chamber was performed. Immediately thereafter streaks of blood emanated from the anterior surface of the iris and after a few minutes the anterior chamber was again half filled with blood. This phenomenon reappeared 3 times before the hemorrhages ceased. Hemorrhages from the iris in leukemia have not yet been described. [M.D.]

A Case of Tumor of the Right Crus Cerebri.
—Professor A. Pitres (*Journal de Médecine de Bordeaux*, January 13, 1901, No. 2) reports a woman of 35 years of age, married, with two healthy children, no miscarriages, and no suspicion of syphilis, who began two years ago to have intermittent headache. Her husband had often struck her on the head, when under the influence of liquor. About a year ago the headache became constant; and for the past 3 months it has been so severe that she could do nothing. A few weeks ago she noticed that her sight was failing, that the left side of her face moved less than the right, and that her left arm was growing weaker. There were no emaciation, fever, vomiting, or constipation, respiratory or urinary troubles. On admission to the hospital 4 main symptoms were found which formed the positive diagnosis of a tumor of the right crus cerebri. These were constant headache, worse at night, with exacerbations, causing the hydrocephalic cry of meningitis; bilateral optic neuritis; partial paralysis of the third cranial nerve on the right side (with dilatation of the right pupil, and paralysis of the superior rectus); and slight paresis of the muscles of the lower half of the left side of the face and the left arm. These last two, together, form the "syndrome of Weber"—positive sign of a peduncular lesion. The patient had an apoplectic stroke the night before, and died upon the day the clinic was held. Sudden death is the rule in these cases. The autopsy showed a glioma the size of a small apple in the right crus cerebri just where it enters the central mass of the right hemisphere.

Infusion of Salt-Solution in the Treatment of Pneumonia.—Dr. Clement A. Penrose, of the Johns Hopkins Hospital, Baltimore, calls our attention to the fact that he recommended this treatment in several cases of extreme severity happening in Professor Osler's wards in that hospital. He says that it had been a custom in the hospital (as it has been doubtless in many hospitals) to resort to infusion of normal salt-solution (.6%) in cases of collapse, especially during or after severe surgical operations. In gynecological cases he had been much impressed by the fact that stimulation to respiration was more marked than to the heart, and this led him to suggest the use of this solution in several cases of pneumonia. His personal experience at the time he read his paper was limited to three cases, of which two were fatal. The success of the treatment, however, should not be gauged strictly by these facts, because all three cases had reached a desperate stage. The infusion of salt-solution was given in the usual manner, at a little above body temperature. The needles were introduced under the breast or in the subcutaneous tissue of the thighs. Care was taken to examine the heart at frequent intervals, especial attention being paid to the pulmonary second sound, and instruments were kept in readiness for instant bleeding if this second sound should have become too accentuated in quality. Inhalation of oxygen was given in a special manner by means of a glass funnel instead of the usual delivery nozzle, and this funnel was held by a framework about two inches above the patient's face and thus supplied the oxygen to both mouth and nostrils without interfering in any way with the breathing. The gas was passed through a bottle containing a pint of hot water in which was placed a mixture composed of creosote, turpentine and benzoin. Dr. Penrose states that since he left the Hospital this treatment has been resorted to in several other cases with most gratifying success. The details of the treatment are given in a paper in the *Johns Hopkins Hospital Bulletin*, No. 100, July, 1899. The author claims that the infusion is a decided advance in treatment, but requires to be used with careful reference to the pulmonary second heart-sound. He thinks that infusion is preferable to transfusion. His idea seems to be that it dilutes the toxins in the blood and promotes their elimination through the sweat glands and the kidneys. He says that it lowers the temperature, stimulates the heart, and

renders the breathing less labored, and he also thinks that it renders the patient more susceptible to the influence of oxygen.

We have practically quoted here his own statements in his paper and must refer the readers to the paper itself for details.

Dr. Penrose says that Dr. Reid Hunt made experiments on dogs with intravenous injection of salt-solution, and found that the injection of this solution caused a marked increase in the amplitude of the respiratory undulations of the blood-pressure. The theory seems to be that the infusion of salt-solution increases the circulation in the lungs and therefore their ability to take up more oxygen. Not sufficient is said, however, about the possibility of such treatment causing a pulmonary edema, a risk which we should suppose on purely theoretical grounds to be a not insignificant one. Dr. Penrose does well to call attention to the need of instant bleeding in case the pulmonary second heart-sound should indicate the overdilatation of the lungs. But this sign is one which we should fear might not be sufficiently accurate or, at least, recognized with sufficient accuracy, to render all danger on this account unimportant. The value of the treatment can only be determined by a wider clinical experience, among a larger number of observers.

The Bio-Chemical Basis of Pathology.—The paper by Dr. Bunker, in the last number of the *JOURNAL*, is worth a careful reading by those medical investigators who take time to give thought to the deep-lying foundations of the science of pathology. Dr. Bunker's paper is not an arraignment of the microscope, for the author is evidently too wise to take such an extreme view; but it contains a frank criticism of that useful instrument, and at the same time it is a clear and comprehensive demonstration of the grounds for its limitations. It must be apparent to the man who takes the time and opportunity to think about it, that the microscope, as an instrument of precision, is an aid merely to one of the senses—the eye—and that what is not revealed to the eye can never be revealed by the microscope. According to Dr. Bunker, morphology has practically reached its limit in the field of research. This concise statement will not be welcome to the school of investigators who seek to find in dead matter the secrets of life and of disease—and it may

indeed be a trifle premature; but it expresses a truth which, if not yet realized, must be forced upon the minds of students of medicine in the not remote future. In the examination of diseased structure the microscope reveals not what is, but what has been; not the process of disease, but merely the wreckage which it has left; not the vital facts, but only the dead relics. The structural changes in a cell, pursued to the remotest conceivable subdivisions of dead cytoplasm, tell only an insignificant part of the story of disease. The essential factors are not shown to the eye, for they consist essentially of bio-chemical forces. They are no more to be seen and apprehended under the lens of a microscope than is the combination of an acid with a base.

The supreme merit in Dr. Bunker's paper is that it serves to call the minds of investigators to the true and ultimate problems of pathology—those problems which lie in bio-chemistry. It serves to divert them from their rather crude and persistent attempts to read in microscopic changes the true science of pathology. If it fully serves this purpose it will do well. It is too conservative not to recognize that the training of the eye by means of the microscope is an essential correlative factor in the study of disease, but at the same time it expresses the problems of disease in formula that cannot be solved by the eye alone, even though this organ were harnessed to a lens a hundred-fold mightier than the hand of man has yet evolved.

A Plea for the Ophthalmoscope.—Although ophthalmology is destined to remain within the exclusive confines of specialism, its creation as a major branch in many medical colleges has offered opportunities to the student-body which unfortunately are not always appreciated until too late. It is remarkable, but true, that many otherwise excellent physicians are not only ignorant of ordinary external ocular affections, but are absolutely unfitted to inspect this important organ as an accessory means of diagnosis. It seems almost incredible that an organ which in its structure practically represents a combination of almost all varieties of normal tissues, which permits of the inspection of exposed nerves and bloodvessels in situ, and in which there arises such a variety of pathological changes, indicative of systemic affections, should be so neglected by the general practitioner. How often is the ophthalmologist consulted as the last court of appeal when some physician has been instilling a mydriatic into a glaucomatous eye, and how seldom is he approached as a first court of appeal when the detection of intraocular changes might have elicited many valuable diagnostic factors. No one, of course, should attempt to perform any operations upon the eye unless he has had considerable experience; but this does not apply to the treatment of simple corneal ulcers and uncomplicated cases of conjunctivitis, which are so frequently

unintelligently treated by the family doctor. The expressions of students and even practitioners regarding their distaste for ophthalmology have their inception in several sources. In the majority of cases these dislikes are due to the fact that in the teaching of other branches of medicine but very little attention is paid to the eye. Again, the subject of "refraction" is taught to those who have preconceived intentions of forever banishing it from their consideration after they have graduated. Notwithstanding that the eye and its appendages consist of fibrous, adipose, areolar, muscular, nervous, vascular, glandular, osseous and specialized tissues, together with serous and mucous membranes, hair, skin, and cartilage, it is given but an insignificant position in modern treatises on pathology. If the intelligent use of the ophthalmoscope by the general practitioner would take the place of his frequent unintelligent use of the test lenses, much would be gained in diagnosis and treatment.

The Case of Major-General Wood.—The *New York Medical Journal*, commenting on our reference to the recent promotion of Dr. Leonard Wood to be a major-general, tells us that the case is not so unprecedented as we had supposed. In support of its criticism it mentions two instances (and only two) of surgeons being promoted in the line; one, the case of "a veterinary officer in an English hussar regiment" serving in a campaign in Egypt, and the other that of General Canonge, who has held high combatant command in the French army. The *New York Medical Journal* omits to give the details of these two cases, so we cannot judge how similar they are to the case of General Wood. Anyhow, the two cases serve as the exceptions that prove what seems to be quite a general rule. The special features that give interest to General Wood's case are not only his promotion in the line, but also his advance to such high rank in so short a time. If there are really parallel cases in any foreign service, we should be pleased to be informed about them, for we do not pretend to have made any extended research in the matter. We are under the impression that even in this country such cases have not been frequent. From the tone of the British medical periodicals in recent years in their comments on the unsatisfactory status of their army medical service, we should be much surprised to hear of an English army surgeon being advanced, for any gallant action whatsoever, to the rank of a major-general in the line. It is not so very long ago, as some of our readers may recall, that a brave English army surgeon in India, who had led a command and done some gallant fighting in an emergency, was referred to by the Duke of Cambridge, Commander-in-Chief of the British Army, as "that brave civilian."

A Bishop on Christian Science.—Bishop Fallows, of Chicago, is to be commended for his critical genius

as well as for his capacity to manufacture a new nomenclature—if the latter is really a commendable thing. He tells his good friends in the church who are inclined to be Christian Scientists, that if they are going to start a new religious system because they happen to have been healed at some time through the influence of a mental law as universal as gravitation, then the people who have been cured by patent medicines have just as good reason to establish medico-religious cults as they have. Thus he suggests that there would be Christian Liver Pillists, Christian Sarsaparillists, Christian Celery Compoundists, and Christian Cholera Mixturists. He might have added a good many more, especially if he had taken their names from the quack advertisements in the religious press. Bishop Fallows is doubtless brought into contact with a good many persons who mix their theology with their therapeutics, and therefore his suggestions are worth heeding. Professor Jastrow, from another range of vision, points out that the doctrines underlying this foolish system are not characteristically religious ones, but that they are only distorted into a religious guise. This criticism is a profound one, and should be a source of comfort to those alarmists who fear that Christian Science will overrun the land. It means that this system is no more a religion than it is a science, and therefore, that it is probably destined to an ephemeral existence. Persecution will help it for a while, but a wise and forceful administration of the laws against it will do much to exterminate it. It is an illegal practice in this State.

The Therapeutic Value of Yeasts.—An editorial in our last number dealt with some of the phases of the complicated problem of yeast fermentation, and this subject very quickly leads to one of practical importance—the current question as to the value of yeasts as therapeutic agents. For a number of years a few clinicians have employed yeasts in the treatment of furunculosis. Baron has recommended this treatment in conjunction with fruit juice in infantile scurvy. Landau employs an injection of brewer's yeast in vaginal gonorrhea, basing his treatment upon the fact that the yeast organisms have greater vitality and propagate more rapidly than gonococci, which are consequently crowded out. Most important are the observations that yeasts may favorably influence the course of diabetes. The effects of yeast upon the intestinal contents, with special reference to the utilization of sugar, make it possible, at least experimentally, for a patient to partake of a liberal hydrocarbon diet without increase of the glycosuria. The method of this action is simple. We know that the yeast causes fermentation of the sugars in the intestines with the production of alcohol and carbonic acid. However, we must recognize that the yeast so introduced has the power of acting only upon the sugars derived from the food, or, in other words,

those present in the alimentary tract. Nobécourt, Hallion and others claim a decided lessening of certain toxins, especially of diphtheria, when yeast has been given. For instance, Hallion found that if he added a pure culture of yeast in the must of beer to a dose of diphtheria toxin this mixture injected into the skin of the guineapig was harmless; but, when the toxin and yeast were injected unmixed in different parts of the body of the guineapig, the action of the toxin was not inhibited. This would indicate that the yeast neutralizes the poison directly. The author has concluded that the acidity of the culture medium is responsible for the neutralizing action on the toxin.

Besides the conditions named in which the use of yeasts is recommended we may also mention their employment in enteroptosis, the gastrointestinal disorders of infancy, the infectious fevers, and sepsis. It may not be unprofitable to summarize rapidly the action of yeasts introduced into the digestive tract. We know that the body temperature is favorable for their development, and that the saliva has no unfavorable influence. The gastric juice destroys a certain proportion of the yeasts introduced, but a certain amount is passed on, still active, into the intestine. In this alkaline medium we are obliged to consider the action of the bile, pancreatic secretion and the microorganisms present in the contents. It has been found that microorganisms do not sensibly affect the vitality of the yeasts. The action of the intestinal juices and the pancreatic juices is not as certain, but we know that the bile exercises a retarding influence. It is found necessary, in order to provide the most suitable medium for the development of yeasts, to add a liberal supply of sugar. Large quantities of yeast produce diarrhea, vomiting, fever and coma, which, it has been pointed out, are probably due to the toxic action of the carbonic acid gas evolved. Before we can intelligently employ yeasts in other than an empiric manner it will be necessary to have established the complete action of the several varieties of yeasts and the precise rationale of this action.

Experiments with the Milk of Tuberculous Cows.—According to the *Popular Science Monthly* (March, 1901) some interesting observations have been made at the Storrs Experiment Station in Connecticut on the use of the milk of tuberculous cows. Experiments, extending over a period of several years, were made by using the milk of a group of diseased cows for feeding calves. During the first two years, when the cows had the disease only in its earlier stages, the calves and young cattle which were fed on their milk and ran with them constantly, presented no symptoms of tuberculosis and showed no reaction to the tuberculin test. During the next year and a half, however, the results were quite different. By this time the disease had progressed so far in three of the cows used for the experiment that their failure was quite apparent. Five calves fed on the milk

from these animals, now well advanced in tuberculosis, proved to be diseased and responded to the tuberculin test. These experiments go to prove, what would almost be accepted without proof, that a cow far advanced in tuberculosis is more likely to transmit the disease with her milk than a cow that was still in the incipient or early stages of the infection. The one practical inference to be drawn is that the danger of infection from tuberculous cows is probably not so great as some persons have feared, because bovine tuberculosis, at least when transmitted to human subjects by milk, is not likely to be so transmitted until the disease is so recognizable as to be easily detected. Still, these observations were made on calves, not on children, and the inference is rather a wide one that is drawn from calves to children. Experiments seem to have proved that pasteurized milk from tuberculous cows can be safely used for raising calves, but this is no argument in favor of feeding such milk to children—or to people in general. Dairymen, as well as veterinarians, cannot be too careful to take no risks in any such way. "Pure" milk does not mean "pasteurized" milk.

The Care of "Neglected" Children.—Crime and vice may be looked upon as symptoms of disease in the body politic, and as such no effort can be too great that is exerted in their prevention, not less than cure. That much crime and vice can be prevented is so obvious a truth that its statement seems superfluous. Unfortunately, we cannot go back 200 years in our influence upon society, but we can at least start 200 years in advance. Inasmuch as "the child," in truth, "is father of the man," we must, in order to diminish crime and vice in later life, prevent its development and growth during the receptive and evolutionary period. Such a noble work the Children's Aid Society of Pennsylvania is engaged in, and it is done most admirably, intelligently, and practicably. The principle followed consists in the individual treatment in homes of the children that come under the care of the Society, which now, after an active existence of 19 years, has on its list 8,000 good homes that have been carefully investigated and inspected, into which, for a small payment at first, the children will be received. The object is to provide the children, not with the reformation that often they do not need, but with the personal care and attention and influence of foster-parents, that they need most of all. That the principle is correct is amply proved by its successful application. The efforts of the Society are directed upon three main lines: The care of foundlings; the securing of work in country families for women with babies; and the care of neglected children accused of delinquency or crime. The last report of the Society, just issued, shows that there were under its care at the beginning of the year 1900, 803 children, and that during the year 140 were additionally received. These are classified as follows: Orphans, 33; half

orphans, 97; deserted children, 39; from dissolute parents, 63; from unmarried parents, 43; from invalid and insane parents, 26; rescued from ill-treatment, 88; from parents living, but separated, 93; from parents unable to control, 42; vagrants, 10; from criminal courts and magistrates, 56; from almshouses, 335; from other charitable societies, 18. Depravity and immorality, like weeds, thrive where neglect and indifference prevail; while good citizens, like choice flowers, must be tenderly watched and carefully cultivated. The work of this Society emphasizes more forcibly than any elaborate argument the wisdom and the economy, as well as one method of preventing crime and vice, and thus by so much lessening the later need for reformatory, prison, and almshouse; and it should receive unstinted support, inasmuch as it represents an inestimable service both to the individual and to the State.

The Association of Appendicitis and Right-Sided Adnexal Disease.—The frequency with which disease of the right uterine appendage and broad ligament is associated with an adherent and inflamed vermiform appendix has attracted the attention of abdominal surgeons to a much greater extent within recent years than formerly. Indeed, the gynecologist is now arming himself for any intestinal complication of the kind when the symptoms would seem to indicate right pelvic disease. It is, however, very often when such a complication is least expected that the emergency arises, and the field of operation is unexpectedly transferred upward to the right iliac region. Persistent bladder-symptoms—frequency of micturition, dysuria, and irritable bladder—may have their origin in the adherence of an inflamed appendix to the body of that organ, while severe paroxysmal colicky pains, closely simulating those of extrauterine gestation or the painful contractions of a tubal abscess, may, at the time of operation, be found to have arisen in a latent appendicitis, with dislocation of that erratic organ to the pelvic region. Every gynecologist has now and again run across an elongated vermiform appendix—which not infrequently does not appear to be inherently diseased—attached firmly to the uterine fundus, broad ligament, tube, or ovary, with extensive pathological involvement of the pelvic viscera. The very frequency of the association would seem to debar the accidental element and to indicate some causal relationship between the two conditions.

Is the appendix attracted to a primary focus of disease in the pelvic organs, drawn thither by the vascular engorgement of the parts, or is it itself the offending agent, and, wandering here and there among the pelvic viscera, does it attach itself arbitrarily to a more susceptible portion of these organs, and through transmission of the pathogenic germs that normally inhabit its lumen, excite in the surrounding tissues an inflammatory reaction?

The tendency for the bacillus coli communis to penetrate the intestinal walls and invade the substance of adherent organs and tissues has repeatedly been noted. A dermoid cyst, pus-tube, or ovarian or uterine tumor may thereby be transformed into a suppurating nidus of grave disease and destruction of tissue. Is it not quite reasonable to suppose in certain of these associated cases of pelvic and appendiceal disease in which the greater pathological changes are to be found in the fallopian tube or ovary, in the absence of the history of septic or gonorrheal disease originating in the uterus or vagina, that the pelvic disease is the direct result of infection from the appendix vermiformis through bacterial transmission? On the other hand, when the adherent appendix appears to be more advanced in the pathological process, and has attached itself by bands of plastic lymph to a comparatively healthy broad ligament, or to the fundus of the uterus or to the bladder, it would naturally seem to be the offending organ primarily diseased and merely attaching itself to whatever chanced to be most in apposition to it.

The obscurity that is unavoidably associated with the etiology of appendicitis necessarily renders any absolute statement as to the primary point of the disease in these pelvic cases impossible. It would seem to us, however, that the origin of pelvic disease from appendiceal infection is more than merely possible, and indeed, quite probable for various reasons, as follows: In the first place, the well-recognized source of infection from intestinal adhesions in cases of suppurating cysts and tumors arising from the pelvis, proves the ready transmissibility of the pathogenic intestinal germs to the surrounding structures. If this complication may arise from ordinary adherent loops of intestine, it is just as reasonable to suppose that it may follow from an adherent appendix when that organ penetrates into the pelvic recesses. In the second place, the frequency of the greater pathological changes being in the adherent structures and not in the appendix itself, would seem to prove that the infection has arisen in a bacterial invasion, the microorganisms not producing the same inflammatory changes in their natural habitat as they would in any adventitious structure into which they might penetrate. In the third place and finally, the aggravated constipation, which is such a common associated condition in the various pelvic disorders of women, by lessening the resisting powers of the body through the resultant toxemia and by markedly increasing the virulence of the pathogenic bacteria resident in the intestinal tract, favor their dissemination through the bowel-wall adherent to the surrounding organs whereby the latter will the more readily become the seat of infection and active inflammatory changes. In some of the right-sided pelvic inflammations, therefore, the possibility of an appendiceal origin should not be overlooked.

Reviews.

An Introduction to Physiology. By WILLIAM TOWNSEND PORTER, M.D., Associate Professor of Physiology in the Harvard Medical School. Pp. 314. Cambridge, Mass.: The University Press. 1901.

The readers of the PHILADELPHIA MEDICAL JOURNAL will recall the admirable paper of Professor Porter (published in the issue of September 5, 1900) on the teaching of physiology. In this paper the advantages of a properly conducted laboratory course of instruction over a purely didactic course, though illustrated by experiments, were clearly, forcibly, and convincingly pointed out.

The method of teaching there outlined has been put in practice at the Harvard Medical School.

In this paper it was also stated that at the very beginning of his studies, the student should acquire a knowledge of physiological methods, should be trained in technic by the study of one or more tissues, the physiology of which is well advanced. For this purpose no departments of physiology are so well adapted as those relating to the physiology of muscle and nerve, and the physiology of the circulation.

The "Introduction to Physiology," recently published by Professor Porter, is intended to meet the requirements of the method advocated by him. It is believed that the subject-matter is "at present that best adapted to form the mind in habits of exact observation and clear reasoning." It is divided into two parts: 1. The physiology of muscle and nerve. 2. The physiology of the circulation.

In Part I, under the title, "Methods of Electrical Stimulation," there is a description of a new form of that valuable instrument, the capillary electrometer, devised by Professor Porter, a new form of rheocord to be used in connection with the electrometer, an account of the electric cell, and a clear presentation of the scientific principles underlying their construction, their mode of action and their mutual adaptation for the study of the phenomena exhibited by muscle and nerve. The phenomena of induction, the construction of the inductorium, the induced currents and their advantages as stimulating agents, are clearly and scientifically presented.

Then follows a brief account of the graphic method, the apparatus employed, and the manner in which it is used in physiological work. The remainder of Part I, pages 59 to 235, is devoted to a consideration of the electrical stimulation of muscle and nerve, chemical and mechanical stimulation, irritability and conductivity, the electro-motive phenomena of muscle and nerve, and the change in form of muscle. Under each heading there are a number of fundamental experiments logically presented, which, if thoroughly and accurately performed, will not only give the student valuable information, but, far better, will train his faculties for the investigation of problems in other fields of physiology.

Part II is devoted to a consideration of the mechanics of the circulation. The cardinal facts are made clear by means of a new artificial scheme also devised by Professor Porter. This, taken in connection with a number of experiments made with the heart of the frog, and observations of the heart and pulse of man, will give the student an admirable idea of the phenomena of the circulation. An objection to the use of this Introduction by other teachers, might be that it will be necessary to have the same apparatus in order to perform the experiments here detailed. This difficulty is easily overcome by buying the apparatus, which we are informed is "trustworthy and relatively inexpensive." The Introduction is cordially recommended to all those interested in the practical teaching of physiology. [A.P.B.]

Society of Biology.—A Society of Biology has been founded in Italy for the purpose of studying biological sciences. The society is divided into sections on anatomy, physiology, pathological anatomy, general pathology, pharmacology, hygiene, zoology, and botany.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

New Department.—A department of Laryngology and Rhinology has been established by the Board of Trustees at the Presbyterian Hospital, 51 North Thirty-ninth street, under the direction of Dr. Arthur H. Cleveland.

New Duties for Pathologist.—Hereafter the pathologist at the State Hospital for the Insane will be compelled to examine the cattle obtained for the institution to ascertain whether they are free from tuberculosis.

Rabies.—Dr. N. G. Keirle, resident physician of the Pasteur department of the City Hospital, has found that a cat which bit several members of a family at Mahanoy City, Pa., nearly a month ago was rabid. The cat, which had been a pet, was killed and a portion of the spinal cord was sent to the Pasteur laboratory. Rabbits inoculated with a tincture made from the spinal cord became rabid.

Practised Medicine 68 Years.—Dr. John Dean Ross, a practising physician, died at his home in Williamsburg, Pa., March 5th, aged 95 years. Dr. Ross was graduated from the University of Pennsylvania in 1832. He founded the Blair County Medical Society, and was its first president. He was president of the State Medical Society in 1865, and was its oldest member at death. He was a member of the American Medical Society 47 years.

St. Joseph's Hospital.—The report of St. Joseph's Hospital for February shows the number of patients admitted during the month in the gynecological, surgical and medicinal clinics to have been 163; remaining from January, 120; total number treated, 283; patients discharged during the month, 160; patients remaining March 1, 123. In the medical clinic there were 165 cases treated; surgical, 394; gynecological, 107; ear, nose and throat, 223; children's clinics, 87; nerve, 60. There were 34 ambulance calls, 32 patrol cases and 92 accident cases.

Assistant Surgeon of the Russian Navy Charged with Desertion.—Leo Alexandroff, an assistant surgeon of the Russian cruiser *Variag*, who was arrested as a deserter, was set free on July 23, 1900, by a decision of the United States Court of Appeals. He came to this country with a crew intended for the *Variag* while the vessel was building at Cramps' shipyards. Shortly after his arrival he took out his first naturalization papers, and was later arrested as a deserter. The surgeon claimed that, as the *Variag* was not in commission, he could not desert from a ship that did not exist.

Deaths in Philadelphia.—The report of the Bureau of Health for 1900 has been submitted. It states that 2,717 deaths have occurred from tuberculosis during 1900. This report gives interesting statistics, of which, perhaps, the most significant is the number of deaths resulting from consumption—2,717. The Board is considering the advisability of recommending to the legislature the placing of this malady on the list of contagious diseases. Pneumonia, it is stated, caused 2,915 deaths during the year; but there was a marked decrease in the number of fatal cases of diphtheria, ascribed to the use of antitoxin. Attention is called to the sanitary need of prohibiting further interments in cemeteries in the central or built-up portions of the city. On the subject of milk, it was reported that 1,684,768 quarts were inspected during the year; and 21,384 were found to contain adulteration of water. Smaller numbers of quarts were found to be adulterated with preservative, or to contain coloring matter. It is recommended that many improvements be made at the Municipal Hospital in the way of interior alterations.

Death of Dr. Richard J. Dunglison.—Dr. Richard J. Dunglison, whose reputation in medical circles need hardly be commented upon, died on March 4 at his home in Philadelphia. Dr. Dunglison was born in Baltimore, Md., November 13, 1834. His father was Dr. Robley Dunglison, a well known physician, and his grandfather, John Leadam, was a noted surgeon in London, England. Dr. Dunglison was a graduate of the Central High School and the Collegiate

Department of the University of Pennsylvania, receiving the degree of A.B. in 1852 and A.M. in 1855. In 1852 he took up the study of medicine under his father's direction, and after a four years' course in the Jefferson Medical College graduated from that institution in 1856. He was the editor of "Dunglison's Medical Dictionary" and many other medical works of reference. He was acting assistant surgeon of the army from 1862 to 1865, and executive officer of a local army hospital during the closing years of the Rebellion. He was a member of the County Medical Society, Mutual Aid Association, State Medical Society, American Medical Association, International Medical Congress and many other organizations, in nearly all of which he held office.

Vital Statistics of Philadelphia for the week ended March 2, 1901:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 2, brain 15, bronchi 11, kidneys 27, lungs 75, peritoneum 8, pleura 1, stomach and bowels 17, spine 2		158
Inanition 21, marasmus 15, debility 4		40
Tuberculosis of lungs		62
Apoplexy 29, paralysis 8		37
Heart—disease of 29, dropsy of 1, fatty degeneration of 1		31
Uremia 12, diabetes 4, Bright's disease 14		30
Carcinoma of bladder 2, stomach 3, uterus 2, jaw 2, liver 1, larynx 1, esophagus 1		12
Convulsions 18, convulsions, puerperal 1		19
Diphtheria	108	20
Brain—disease of 1, dropsy of 2, softening of 3		6
Typhoid fever	18	6
Old age		10
Cyanosis		4
Scarlet fever	91	9
Influenza 14, abscess of lung 1, abortion 1, asthma 1, anemia 1, aneurysm of aorta 1, burns and scalds 4, casualties 7, cerebrospinal meningitis 1, congestion of brain 1, congestion of lungs 4, pelvic cellulitis 1, cirrhosis of liver 5, childbirth 1, tuberculosis of the bowels 1, carbuncle 1, croup 1, membranous croup 7, diarrhea 2, drowned 1, dysentery 1, erysipelas 3, catarrhal fever 1, fistula 1, gangrene of foot 1, hemorrhage from stomach 2, neuralgia of heart 3, obstruction of bowels 2, edema of lungs 1, poisoning 1, rheumatism 3, sclerosis of spine 1, surgical shock 1, septicemia 6, sarcoma of breast 1, lung 1, suicide 3, teething 2, brain tumor 2, ulceration of stomach 1, whooping-cough 1		94

Pathological Society.—At the meeting of February 26, Dr. R. N. WILSON, JR., reported for himself and Dr. R. H. HARTE a case of **primary carcinoma limited to the vermiform appendix**. The patient was a woman of 24, with a negative family history, who had had several attacks of pain over the appendix and also in the right lumbar region. Diarrhea with bloody stools also was present at times. Operation revealed a long appendix, apparently normal, and no adhesions. The appendix was removed and sectioned. The lumen was obliterated nearly its entire length and at one point was found a typical carcinomatous growth. Dr. Wilson believes that the carcinoma could not have been diagnosed. The blood-count was normal and no tumor showed even when the appendix was removed. The prognosis in these cases is an interesting question. Dr. Wilson thinks that the seriousness attaching to them has been exaggerated. If the prognosis is unfavorable it would suggest the propriety of removing the appendix immediately in every case with appendicular symptoms.

Dr. D. J. M. MCCARTHY and M. P. RAVENEL exhibited a specimen of **melanosis of the cerebrospinal membranes from a case of rabies**. The specimen was from a cow that had died of hydrophobia. All the membranes were affected, but neither the cord nor brain showed any changes. The intense deposit of melanin was not considered to have any connection with the cause of death.

Dr. WILLIAM S. WADSWORTH spoke on **injuries to the brain**. The relation between the resisting powers of individuals and the injuries received was discussed and their significance pointed out.

Dr. M. B. HARTZELL reported a case of **lenticular cancer of the skin**. The lesion appeared first on the sole of one foot and was removed. It afterward spread to the legs, trunk, and face, death of the patient ensuing.

DR. JOHN B. ROBERTS showed specimens of **multiple tumors of the sciatic nerve** which he had recently removed from a patient, 36 in all having been removed.

Academy of Surgery.—At the stated meeting held March 4, DR. RICHARD H. HARTE presented a patient showing the result one year after an operation for **sarcoma of the antrum of Highmore**.

DR. CHARLES H. FRAZIER exhibited a patient showing a peculiar **neuropathic affection of the bones**. Skiagraphs showed a thickening of the left tibia and fibula and exostoses projecting into the right knee-joint with thickening of the ends of the bones.

DR. R. H. HARTE read a paper entitled **some observations on compound fractures of the skull based on 146 cases**. In doubtful cases of fracture an incision should be made through the skin over the point of injury. If infection has taken place a drainage tube may be inserted, but it should seldom extend beneath the edge of the bone. Trephining is not a serious operation, all but 3 of 26 cases recovering. Opium is one of the most useful remedies in use in these cases. Of the deaths 87% occurred during the first 24 hours.

DR. JOHN H. GIBBON reported **two cases of left cecal hernia**. Both patients were males. From a resumé of the literature the conclusion is reached that this variety of hernia is rare in women. The causes are believed to be a small movable cecum and a previous hernia of the small intestine.

DR. FRANCIS T. STEWART (by invitation) reported a case of **cecal hernia with volvulus of the ileum**.

DR. JOHN B. DEEVER read a paper entitled **mortality in operations for obstructive jaundice**. Hemorrhage, cholemia, and shock are the causes of death in the majority of cases. Peritonitis is not a common cause. To prevent hemorrhage chlorid of calcium in 30 grain doses may be given for several days before and after operation, although Dr. Deever has not seen any great benefit from its use. Suprarenal extract seemed of value in one case. The medical treatment of these cases is always disappointing. Early operation is the best preventive of hemorrhage and other complications.

DR. THOMAS S. K. MORTON read a paper entitled: **Report of a case of strangulated femoral hernia; herniotomy; acute obstruction 3 weeks later; enterectomy; recovery**. The case brought up the question of deciding what bowel to return and what to excise when operating for hernia. Dr. Morton returns all bowel that retains its endothelium.

DR. GEORGE ERETY SHOEMAKER spoke on the **Treatment of suppurating hematocele following extrauterine pregnancy**. When the abdomen is opened and this condition found, the abdomen should be closed and the collection evacuated through the vagina. The vaginal route should not be used when operating for extrauterine pregnancy.

Registration of Tuberculosis.—The following tract has been published for gratuitous distribution by the Pennsylvania Society for the Prevention of Tuberculosis:—Tuberculosis, or consumption, as it is usually called, is a contagious disease. The contagion centers around the person who has it, so that he as well as the place in which he dwells are liable to give the disease to others. But the contagion is confined to the matter given off from the diseased part, such as sputum which comes from diseased lungs, or matter which comes from a sore; and this contagion can be destroyed when such sputum or matter is given off, thus making the person of the consumptive, as well as the place in which he lives, harmless to others.

To do this, certain knowledge and means are necessary. Where is this knowledge and means to come from? Under our system of government from the Board of Health. But how is the Board of Health to know who needs them? *Only through registration of every case of tuberculosis.*

Now there are a great many people who seem to think that registration of tuberculosis means putting a yellow label on every consumptive's house, or tying a yellow ribbon on his coat, so that the poor consumptive may be branded and shunned like Cain. Nothing could be farther from the truth.

The only objects which can be obtained by registration of tuberculosis are: 1. To give knowledge and help to the consumptive and his family for their protection and for the protection of the public. 2. To protect people against the danger from contaminated houses into which they may innocently move. As things are now, a family may run into danger which they cannot see. If the house has been occupied by a consumptive, some member of the family moving in is very likely to get the disease. If every case of tuberculosis were registered, the Board of Health could watch houses which are occupied by consumptives and require their disinfection when vacated. To properly disinfect a house is rather an expensive operation, and this being the case few landlords will do it except under compulsion. No one can compel a landlord to disinfect such a house except the Board of Health, and the Board of Health cannot do so unless it knows where the house is.

Registration of tuberculosis would indeed be one of the greatest blessings possible to the people, and especially to the poor people. There would be no publicity in the matter. The sufferings of the consumptive poor would be lessened because they would be at least known to the authorities. The fact is we have all grown so indifferent about the existence of consumption and so callous about the sufferings of the consumptive that we seem oblivious of them. The poor consumptive could not be more completely hidden in the desert than he is in our midst. He needs to be discovered. He needs public attention and only through registration can he get it.

If you desire to join the Pennsylvania Society for the Prevention of Tuberculosis, a remittance of \$1 to the Secretary, 2024 Pine street, Philadelphia, or to The Commonwealth Title Insurance and Trust Co., Treasurer, 813 Chestnut street, Philadelphia, will secure membership.

College of Physicians.—At the meeting of March 6, DR. W. W. KEEN exhibited a modification of Fell's apparatus for artificial respiration. The bellows has an opening in which a funnel containing cotton can be placed for the purpose of giving an anesthetic, if desired. To the tube leading from the bellows can be attached a face-piece or a modified O'Dwyer intubation apparatus, which, when inserted, closes the opening of the larynx. A thumb is held over the end during inspiration (the tube being attached at the side) and removed during expiration. The apparatus is believed to be extremely useful in two respects: First, in surgical operations about the chest; second, in cases of opium poisoning, etc.

DR. GEORGE W. CRILE, of Cleveland, Ohio, gave, by invitation, an address on **experimental research into surgical shock and collapse**, and presented stereopticon views of blood-pressure charts, etc. The experiments were made on upward of 250 dogs, all of which were under surgical anesthesia and were killed before consciousness was regained. The effects on blood-pressure and respiration, of cutting, bruising or burning the various tissues of the body were detailed. The effect produced by sawing or cutting bone, cartilage or fascia was very slight. Wounds of muscle gave more change and in nerve-trunks the effect was very marked, there being an immediate rise of blood-pressure. Opening joints produced little effect. In amputations and disarticulations the principal change was caused by cutting the skin, muscles and nerve-trunks and not by sawing the bone or opening the joint. This exactly opposes the old view. Cutting the skin produced everywhere a marked effect (greatest over the abdomen), the change being greater than for any other tissue except the nerves. Cutting or crushing the tongue produced but little effect, but drawing it forward with considerable force, particularly if toward one side, sometimes caused total inhibition of the heart. The clearing of the throat by vigorous anesthetizers and the inhibition of respiration which sometimes follows and is supposedly remedied by drawing forward the tongue, suggested the above experiments. Foreign bodies thrust into the pharynx and larynx caused marked inhibition, in some instances collapse. Interference with the laryngeal mucosa caused respiratory inhibition and, if marked, cardiac inhibition also. The upper part of the larynx is most sensitive. When the superior laryngeal nerves were severed, these effects were not produced. Cases of quick death from drowning are believed to be due to circulatory failure and not to asphyxia. In positive inflation of the lungs circulation may possibly be stopped, an

important point in cases of resuscitation. Manipulation of the peritoneum caused marked arrhythmia of respiration and, when long continued, complete failure. These changes were more marked as the region of the diaphragm was approached. Handling the omentum caused no change. Opposite effects were noted in the male and female genital tracts. In the former the change, if any, is a fall of blood-pressure. In the latter the blood-pressure rises. Regarding the effect of blows upon the pit of the stomach, experiments led to the conclusion that no amount of manipulation of the solar plexus could produce collapse. The effect is due to action upon the heart, as blows upon the stomach, diaphragm, or intestines will not produce it. The symptoms of asphyxia were compared with those of inhibition. Asphyxia is generally blamed for the sudden deaths which occur during intubation or the removal of a foreign body from the larynx. Experiments showed that it is impossible to produce sudden death by asphyxia. Respirations are more intense when true asphyxia comes on and it takes from 2 to 8 minutes to cause death. These sudden deaths are caused by reflex inhibition of respiration and the heart through the superior laryngeal nerves. Dr. Crile then spoke of the various causes of collapse. Shock is believed to be caused by impairment of the vasomotor nervous system, as shock cannot occur without low blood-pressure. The heart still beats, but pressure is only slightly raised. The pulse is small because the blood does not get back to the heart in sufficient amount to raise venous pressure and consequently arterial pressure. DR. BRINTON mentioned having seen very great collapse from division of the thyroid isthmus and asked if experiments regarding it had been made. DR. CHARLES FRAZIER asked if spinal anesthesia had been used in any of the experiments. In answering these and other questions DR. CRILE stated that he had found nothing in the thyroid isthmus to cause such effects, and thought they were probably due to the traumatism on the larynx itself. Experiments with spinal anesthesia showed that no changes in blood-pressure or respiration were caused by operations upon the anesthetized area. The experiments had led to no plan of treatment for shock, as they were more suggestive of prevention than of cure. As to the part played by hemorrhage in causing shock, there is no fall in blood-pressure from hemorrhage up to a certain point, as the heart and vasomotor system compensate for the loss of blood. But because of the diminished stock of reserve power, shock comes on more easily after hemorrhage. The continuance of shock after abdominal operations depends upon the amount of raw surfaces left, the tension of stitches, amount of blood-clot left, etc. These factors probably determine why one surgeon's patients recover from operative shock sooner than do those of another operator. The statement was repeated that the cause of death in cases of quick drowning is blocking of the circulation instead of asphyxia.

College of Physicians of Philadelphia—Section on Ophthalmology.—Meeting, February 19, 1901. Dr. William Thomson, chairman, in the chair.

DR. WM. ZENTMAYER exhibited a case of **synchysis scintillans** occurring in a woman, aged 40 years. The condition was monocular, affecting the right eye. The crystals were diffused throughout the entire vitreous, and in places were imbedded in the retina. The fundus was otherwise normal. Dr. Zentmayer also showed a man, aged 43 years, with **hyaline formations on the optic nerve head**. The entire temporal half of the disc and the lower inner portion, in places, was covered by a mass composed of clusters of brilliant grayish-white bodies. There were similar bodies in the choroid surrounding the lower outer portion of the disc. The left eye presented the same condition in a less marked degree. Both nerves were very slightly atrophic. In the discussion DR. DE SCHWEINITZ showed a microscopic slide of an optic nerve which had ophthalmoscopically presented all the appearances that were seen in Dr. Zentmayer's case. DR. CARPENTER referred to 5 cases which he had reported several years ago, in only one of which were the drusen bodies found both in the macular region as well as on the nerve head.

DR. G. ORAM RING exhibited a young girl, 9 years of age, with **paresis of the left internal rectus following diphtheria**, which unlike most of the cases that he had seen, showed no improvement after 9 months' time.

DR. JOHN T. CARPENTER gave the clinical history of a case of **melanotic sarcoma of the choroid** in a woman, aged 64, of poor health and with probable malignant disease of the liver.

DR. H. F. HANSELL read a paper on **Binocular hemianopsia and optic-nerve atrophy in a case of diabetes mellitus**. The patient, a woman, 56 years of age, had suffered for a number of years with diabetes mellitus. The eye-symptoms commenced 6 months before she came to the eye department of the Jefferson Hospital. The ophthalmoscope showed marked optic-nerve atrophy of each side without signs of previous papillitis. The perimetric measurements disclosed an irregular hemianopic field for white and a definitely outlined hemianopic field for colors. Vision had declined to $\frac{20}{200}$. DR. DERCUM, who saw the patient in consultation, believed that the diabetic and the optic-nerve atrophy were both due to the same cause, namely, intracranial lesion, probably of the floor of the fourth ventricle. The urine contained $\frac{1}{2}\%$ glucose and was of high specific gravity; it was free from albumin. The case is of interest in that it demonstrated the rare form of eye complication, namely, optic atrophy with hemianopsia without opacity of the media or history of inflammation. Dr. Hansell reviewed the recent literature. In the discussion, DR. DE SCHWEINITZ thought that the symmetrical changes in the visual fields in diabetes mellitus might be explained by the action of the toxin of this disease on the ganglionic cells of the retina. The degeneration in the ganglionic cells results in atrophy of the macular fibers, which later spreads to other bundles. The action of the toxin of diabetes under these circumstances is similar to that of certain drugs; for example, quinin, filix mas, methyl alcohol, etc.

DR. S. D. RISLEY, under the title of Clinical Memoranda, presented Case I, **black cataract**, in a man, aged 74, a native and resident of the island of Barbadoes. Eight years before, an unsuccessful attempt had been made by a local surgeon to extract the lens in the right eye after an iridectomy for glaucoma. Dr. Risley found the ball shrunken, tender to palpation, and evidently causing sympathetic irritation in the fellow eye, a contracted field, increased tension, and a black cataract. The right eye was enucleated, a broad peripheral preliminary iridectomy made on the left, and 6 weeks later the lens successfully extracted in its capsule. The eye recovered without accident, and in 5 weeks, with correcting-glasses, $+5. \text{C} + 8. \text{C}$, $\text{Ax. } 180^\circ$, $\text{V.} = \frac{1}{12}$, with some difficulty. Through this correcting-glass a distinct but apparently not very deep glaucomatous cup of the optic nerve could be made out. Case II was that of a man, aged 58, a patient at the Wills Eye Hospital, presenting **extraordinary calcareous deposit in the tarsal conjunctiva**. He was the victim of chronic trachoma, erosion of the borders of the lids and closure of the lacrimal puncta in the upper and lower lids in both eyes. The entire surface of the conjunctiva was occupied by a pavement of yellowish-white masses that exuded through the overlying soft tissue under pressure. A portion of this was collected, treated with dilute acetic acid, and evaporated to dryness. This was once more dissolved with dilute acetic acid, filtered, and a drop of ammonium oxalate test-solution added, which showed the characteristic precipitate of calcium oxalate.

DR. G. E. DE SCHWEINITZ described some **unusual choroidal lesions associated with pregnancy**. A case of unilateral neuroretinitis beginning in the fifth month of pregnancy resulted in complete disappearance of the neuritis, but left an extensive pigmented retinochoroiditis. He was inclined to think that the retinal and choroidal lesions began simultaneously, although it was possible that the retina was first affected and the choroid coat became involved later, as in several other similar reported cases. In the second case the lesions were those of a bilateral choroiditis, or rather retinochoroiditis, which somewhat resembled pigmentary degeneration of the retina, and were ascribed to the influence of an abortion about the third month. It was suggested, however, that a syphilitic affection prior to this date might have been the cause both of the choroidal lesions and of the abortion.

DR. DE SCHWEINITZ also described a case of **normal combined cataract extraction in which the anterior chamber was not reformed until the thirty-second day**. Although the upper part of the cornea was slightly hazy, vision was $\frac{1}{12}$, but the eye remained red and lacrimation was

excessive. Two and one-half months later keratoiritis suddenly developed, followed by three or four attacks of secondary glaucoma, in one of which the anterior chamber became filled with blood. Vision was reduced to light-perception. Under the influence of profuse diaphoresis produced with pilocarpin and large doses of salicylate of sodium, all inflammatory symptoms disappeared, and ultimately the vision rose to $\frac{1}{2}$, with proper correction, in spite of extensive corneal opacity. The slow closure was attributed to failure of reparative power due to the mental condition of the patient, which was greatly depressed. The late keratoiritis was ascribed to irritating and doubtless infecting secretions from the conjunctiva which obtained entrance through an imperfectly closed wound, because even when the anterior chamber was apparently restored, it is probable that the wound was not perfectly solid. The secondary glaucoma was doubtless caused by sudden complete closure of the wound as follows: Slight leaking from the anterior chamber through an insignificant fistulous opening prevented a rise in tension; when this perforation closed there was complete restoration of the anterior chamber, but the aqueous could no longer find an outlet through Fontana's spaces, which had become impervious, and hence the rise in tension and glaucoma. Dr. Knapp has reported analogous cases, and suggested such an explanation. The great value of pilocarpin diaphoresis was emphasized.

County Medical Society.—The first paper at the meeting of February 27 was read by DR. ELIZABETH L. PECK, who reported two cases of typhoid fever and a case of suppurating bronchial glands, with recovery. The first case of typhoid fever reported was remarkable because of the high temperature, the limit of the thermometer being reached and maintained for some days. The patient was a very nervous woman, the high temperature being ascribed to that cause. Sponging failed to reduce it, the patient seeming to do better when left alone. The second case was that of an epileptic, the convulsions continuing throughout the attack.

DR. MATTHEW WOODS read a paper on the **Registration of tuberculosis from the standpoint of private practice.** Dr. Woods strongly opposes compulsory registration. He believes it would cause a disturbance without being a benefit to either the sick or the healthy. Persons who have been registered may be denied employment. The keeping of a knowledge of his disease from a sick person is often the most beneficent act a physician can do. Registration will not allow this. The fear of registration will have a tendency to keep people from seeking medical advice, until it is too late. Consumption is not contagious. Some people have tubercle bacilli in their sputum and not the disease, and *vice versa*. The Board of Health can accomplish more by eliminating the slums of the city than by making registration compulsory. Physicians can accomplish much by inculcating sanitary laws.

DR. LAWRENCE F. FLICK read a paper entitled **Home treatment of tuberculosis.** In the treatment of this disease three points are to be aimed at: 1. The restoration of the physiological functions of the body. 2. The securing of hypernutrition. 3. The conferring of immunity. These can be best secured, in the case of the poor, by treatment at home. "Close" treatment refers to sanatoria; "open" treatment to the home. The paper of Dr. Flick was an outline of what he characterizes close treatment at home. Early diagnosis is the first point and in this the general practitioner should be more alert. Indigestion is one of the earliest symptoms and its persistence always calls for physical examination of the lungs. When the diagnosis is made the first step should be to inform the patient of his condition. This is necessary to secure his cooperation in the treatment which he should understand is to be a struggle—perhaps from 3 to 5 years in length. Patients are often not cured when they seem to be, and treatment should be kept up for some time after a favorable result is obtained. A daily routine of life as to food, exercise, etc., should be laid down. Abundance of food is necessary—3 to 6 quarts of milk and 6 to 12 raw eggs daily can be taken by many patients. The foundation principle of medication for these cases is that whatever builds up the system is good for the patient. In Dr. Flick's experience the iodine compounds are first in value. Next is creosote given in hot water before

meals, a maximum of 50 drops three times daily being attained in some cases. Strychnin, arsenic, phosphorus, digitalis, and iron are also of value. Use any drug that will help any organ. One of the greatest difficulties encountered in the treatment of tuberculosis is the occurrence of complications as colds, influenza, or pneumonia. These frequently cause a recrudescence. When they occur, absolute rest in bed for several weeks must be insisted upon. Dr. Flick's results for the past 6 years have been 18% of cures, with arrest of the disease in 10%, very great improvement in 26%, and temporary improvement in 19%.

In discussing the two last papers, DR. J. C. WILSON stated that the diametrically opposed views of the speakers was not to be deplored, as a controversial spirit served to bring out the subject more fully. While commending the treatment laid down by Dr. Flick, he believes it impossible to carry out these measures among many of the inhabitants of the city, especially the foreign element in the southeastern section. Because of this, the profession must organize and insist that the municipality provide hospitals for poor consumptives. The drugs used today are the same as were formerly employed, but their application is different. Three groups are included—the phenol, iodine, and arsenical. Regarding registration he believes the way to meet a foe is to seek it and thinks that Dr. Woods in his opposition overlooks the value of that movement to society at large. Consumption is a constant menace under certain circumstances, and registration will help to minimize the danger. DR. R. G. CURTIN uses guaiacol, quinin, strychnin, and nuxvomica in the treatment of tuberculosis. He believes the cases of contagion are few. Instances were cited from the Philadelphia hospital where men had lived with consumptives for years, one man who had an ulcerated throat being there for 10 years, and did not develop the disease. Sentiment against consumptives is getting so great that they seem to have no place, and they are constantly depressed by everybody being afraid of them. DR. J. M. ANDERS said that a certain small percentage of cases of tuberculosis get well without any treatment or change of climate, but systematic treatment will add to this number. Considering this fact, too little attention is being paid to cases that must be treated at home. He has no experience with the iodine compounds. Creosote is not a specific, but it controls the bronchitis, fever, and cough as no other drug will do and is the most valuable single remedy. Fats, as cod-liver oil, are of great value. Arsenic and digitalis are of service, but hygienic measures are of infinitely greater importance. The patient should occupy the largest room available in the house and during the summer live out of doors, in a tent, in the woods, if possible. Plants and flowers in the sleeping apartment are of benefit. DR. ANDERS is in favor of registration. Although pulmonary tuberculosis is feebly contagious, the foci of the disease should be located, and for this reason registration should be secured. DR. S. SOLIS-COHEN said that persistent hopefulness on the part of the physician was a necessary part of the treatment. The patient should be told exactly what his condition is. This does not tend to depression, as hopefulness of the patient is characteristic of tuberculosis. DR. COHEN is not convinced that registration is the best way to accomplish what is desired in the way of hygiene, etc., but he is willing to be convinced. Prophylaxis in this disease is not so much a medical question as it is an economic one. There are three easily separable main stages in tuberculosis—the trophic, the bacillary, and the phthisis or consumptive. Perfect recoveries from each stage have been seen. Pneumatic measures are of great value in the treatment, simple and inexpensive ones being readily devised. Treatment may be summed up in one word—nutrition. DR. A. V. MEIGS believes that compulsory registration would not accomplish what is claimed for it, and that if adopted it will sooner or later fail and be abandoned. The diagnosis of tuberculosis is often so difficult that physicians can exercise great latitude in reporting or not reporting cases. He believes that the Board of Health has not the authority to enforce this measure at present. DR. MEIGS also stated that the committee, consisting of Drs. Mitchell, Tyson, and himself, that was appointed to appeal to the Board of Health in regard to the placarding of houses containing contagious diseases, had been unofficially notified by the president that the Board had receded from its position and that in the future

more discretion would be allowed in the matter of placarding. It has been found that this rule of placarding will not work, and the same thing will be true of compulsory registration of tuberculosis. Tubercle bacilli in the sputum are not an absolute indication of pulmonary tuberculosis.

A paper by DR. LEON BRINKMAN, entitled **Observations: Results of 150 operations for appendicitis**, was read by title.

NEW JERSEY.

Physicians Resign.—Dr. Frank H. Glazebrook and Dr. Henry P. Merrill, Jr., house physicians at the Orange Memorial Hospital, at Orange, N. J., have resigned. They state that their resignation was due to a disagreement with the Board of Governors of the hospital.

Morris Plains Hospital.—A resolution has been introduced in the legislature of New Jersey, calling for an investigation of the Morris Plains Hospital for the Insane. This action has been hastened because of a case in which it was charged that the wife of a citizen has been committed to the asylum when her friends believed her to be sane. She has recently been adjudged in possession of her right mind and was released.

DELAWARE.

An amendment has been introduced in Delaware providing that whenever a physician who is a resident of the State and who was duly qualified to vote for representatives in the General Assembly at the last general election prior to his application shall apply to the State Board of Medical Examiners for a certificate, it shall grant it without examination upon his presenting to the board a diploma from a reputable medical college, and on satisfactory proof that he had been in active practice of his profession at least ten years in any other State of the United States.

NEW YORK.

Physician for Lunacy Commission.—The Senate has passed the bill of Senator Brackett providing that the vacancy in the Lunacy Commission now existing may be filled by Gov. Odell from the ranks of physicians who are alienists or who have for two years been in charge of the insane.

Section on Railway Surgery.—A joint session of the Section on Railway Surgery with the Medico-Legal Society of New York will be held on Monday, April 15, 1901, in New York City, under the chairmanship of Dr. Charles K. Cole, of Helena, Montana. An attractive program, which includes a banquet, is being arranged.

Vaccinated Burglar and the Detectives.—A burglar walked into a quarantined apartment-house in New York City last week. There had been some smallpox in the building and two Board of Health doctors were in charge of the house. They found the burglar at work, and before turning him over to the authorities they vaccinated him. When three detectives arrived at the house the Board of Health doctors would not let them out of the building until they had submitted to vaccination.

Regulating Sale of Poisons.—The following restrictions regarding the sale of poisons have been introduced in the State of New York: No substance which, in the words of the law, "according to standard works on medicine or materia medica, is liable to be destructive to human life in quantities of 60 grains or less, shall be sold at retail or furnished without being labeled with the name of the article and the word 'poison' and the name and place of business of the seller plainly printed in red ink." A record must be kept of the more dangerous poisons, as arsenic, cyanid of potassium, hydrocyanic acid, cocaine, morphin, strychnin, and all other vegetable alkaloids and their salts. A complete record, including the name of the purchaser, his address, the amount of poison sold and date of sale, must be kept where it can be inspected at any time by the proper authorities, and must be preserved for five years.

The Buffalo Academy of Medicine held meetings during the month of February, 1901, as follows:

Section on Surgery.—Tuesday evening, February 5. Program: Conservative Surgery of the Extremity, CHAUNCEY PELTON SMITH. Surgical Complications of Typhoid Fever, VERTNER KENERSON. Operative Treatment of Tubercular Lymphomata of the Neck, PRESCOTT LEBRETON.

Section on Medicine.—Tuesday evening, February 12. Program: The Value of Clinical Pathology, A. E. WOERNERT. Pemphigus, with the Record of a Case, J. W. GROSVENOR. Discussion by GROVER WENDE. Report of a Case of Psychical Equivalent of Epilepsy, CHARLES CARY and JULIUS ULLMANN.

Section on Ophthalmology, Otology, Rhinology and Laryngology.—Monday evening, February 18. Program: Presentation of a Case—Macular Choroiditis, with Cholesterol Crystals, J. C. CLEMESHA. The Eye in Nervous Diseases, W. C. KRAUSS. Certain Diseases of the Eye Benefited by Treatment of the Nose and Nasopharynx, B. H. GROVE.

Section on Pathology.—Tuesday evening, February 19. Program: Leukemia, CHARLES S. JEWETT. House Distribution of Cancer in Buffalo During the Past Twenty Years. IRVING P. LYON. Formaldehyd Gas—Its Most Simple Application and its Limitation in Household Disinfection. WILLIAM G. BISSELL.

Section on Obstetrics.—Tuesday evening, February 26. Program: The Toxemia of Pregnancy, M. A. CROCKETT. Symphysiotomy, P. W. VANPEYMA.

Manhattan Dermatological Society.—A regular monthly meeting was held at the residence of Dr. Jacob Sobel, No. 1828 Madison Avenue, on Friday evening, March 1, with Dr. William S. Gottheil in the chair.

DR. L. WEISS presented a case of **erythema multiforme** of the face, showing grouped and scattered papules assuming a semivesicular nature, and circular patches of the forehead. On the extensor surface of the right leg a nodule resembling erythema nodosum had existed for two weeks. DR. SOBEL agreed with the diagnosis of exudativum annulare and DR. GOTTHEIL stated that the face was commonly involved in erythema multiforme.

DR. SOBEL presented two cases of **pruritus hiemalis**. Both patients attributed the itching to the cold weather, one having had repeated attacks. The urine was negative, there was no gastrointestinal disturbances and no signs of pediculosis. The body above the umbilicus was free. DR. WEISS concurred in the diagnosis. In winter-itch there are so-called prurigo papules, which are more visible to the touch than to the eye. DRS. GOTTHEIL and ABRAHAMS considered the first case a papular eczema. DR. COCKS looked upon both as pruritus.

DR. WEISS showed a patient with a **sycosis simplex** of the left cheek and neck, the lesions in the latter region resembling furunculosis. DR. ABRAHAMS looked upon the condition as sycosis plus furunculosis. DRS. BLEIMAN and GEYSER as a sycosis; and DR. GOTTHEIL as a furunculosis.

DR. ABRAHAMS presented a case of **erythema simplex** of the face in a highly neurotic woman. The condition assumes a butterfly shape.

DR. ABRAHAMS showed a case of **rheumatic purpura** which had existed, with remissions, for 20 years. The lesions respond rapidly to salicylates. DR. SOBEL would diagnose peliosis rheumatica and give salicylates. Relapses are not at all uncommon in this affection. DR. GOTTHEIL remarked that most cases of rheumatic purpura occur in children and young people.

DR. ABRAHAMS presented a patient who showed in the prepatellar region a large, firm, bluish-colored, flat mass, about the size of a child's palm. Six years previous the woman noticed a small lump around a varicose vein; this increased in size, remained stationary for 2 years, and then steadily increased to its present dimensions. He inclines toward a diagnosis of **sarcoma cutis**. DR. OBERNDORFER thinks it nonmalignant, probably a fibroma. Microscopical examination is advised. DR. FRANKLIN thinks that microscopical examination would settle matters, and with the aid of clinical observation give a positive diagnosis. DR. COCKS considers it benign. DR. WEISS would call it fibro-cavernosa, and DR. GOTTHEIL angiofibroma.

DR. ABRAHAMS reported a **lupus erythematosus** of the face, followed in 6 months by a **lupus vulgaris** of the left breast, the latter diagnosis being substantiated by micro-

scopical examination. DR. GOTTHEIL presented photographs of sarcoma of the abdominal wall and of congenital hypertrophy of all structures of the third and fourth fingers of the right hand. DR. MEYBOWITZ remarked that such anomalies were usually stigmata of degeneration.

State Health Commissioner.—Gov. Odell appointed Dr. Daniel Lewis, of New York City, State Health Commissioner on February 28 and sent his name to the Senate for confirmation. Dr. Lewis was president of the State Board of Health, which has been legislated out of office. He held the presidency of the board for three terms, serving on it since 1895. His appointment as State Health Commissioner is for the term ending December 31, 1904. The salary of the office is \$3,500 per year. He will have entire jurisdiction over the matters which have hitherto been supervised by the State Board of Health.

NEW ENGLAND.

Resignation.—Dr. B. H. Cheney, for 3 years chairman of the Board of Physicians and Surgeons of Grace Hospital, of New Haven, Conn., and Mrs. Cheney, his wife, chairman of the Women's Board of the institution, resigned their positions on March 1, 1901.

New Haven Hospital.—Plans have been completed for the new clinical building to be erected near the New Haven Hospital. The new building will be situated on the corner of Congress Avenue and Cedar Street, just across from the City Hospital. The frontage on Congress Avenue will be 65 feet, and the depth on Cedar Street, 90 feet.

Prize Essay.—Dr. J. B. Learned, of Northampton, Mass., is continuing his agitation against the practice of administering drugs to induce sleep. He believes that other methods, more natural and less harmful and destructive, are practicable, and offers, through the *Journal of the American Medical Association*, a prize of \$100 for the best essay on the subject.

CHICAGO AND WESTERN STATES.

Dr. Schauer Resigns.—Dr. J. L. Schauer, professor of dermatology in the Milwaukee Medical College, resigned on March 1, 1901.

The American Dermatological Association.—The Association will hold its next meeting in Chicago, May 30 and 31, and June 1, 1901.

Medical Society of the Missouri Valley.—The semi-annual meeting of this society will be held in the city of Omaha, on Thursday, March 21.

The Western Ophthalmologic and Oto-Laryngologic Association.—The Association will meet in its next annual session in Cincinnati, Ohio, April 11 and 12, 1901.

Association of Iowa Physicians.—President, Donald Macrae, Council Bluffs; vice-president, F. E. Sampson, Creston; treasurer, W. B. Small, Waterloo; secretary, J. W. Kline, Ft. Dodge.

Diphtheria in Springfield.—The residents of Springfield, Ill., have become quite alarmed on account of the spread of diphtheria in that city. The disease is of the malignant type, and several deaths therefrom are reported.

Chair of Casualty Surgery.—Dr. Gustavus Blech has been appointed professor of casualty surgery in the Jenner Medical College. This is the first institution in the West to establish a chair for this branch of practical surgery and medicine.

Hospital at Oshkosh.—Dr. C. W. Oviatt, house surgeon at St. Mary's Hospital at Oshkosh, Wis., announces today that plans have been completed for a \$50,000 hospital to be built in the business portion of the city. At the present time \$40,000 has been subscribed.

Pomona Valley (Cal.) Medical Society.—At the meeting of this Society, in Pomona, January 31, the following officers were elected: Dr. Conley Heaton, Pomona, presi-

dent; Drs. William A. Lillie, Ontario, and D. Hardy Smith, Pomona, vice-presidents; and Dr. Edward Henderson, Pomona, secretary and treasurer.

Milwaukee Hospital for the Insane.—The following officers were elected for the ensuing year at the annual meeting of the Board of Trustees: President, B. B. Hopkins; vice-president, A. L. Cary; secretary, A. F. Wallschlaeger; *ex officio* treasurer, the county treasurer, Schultz; executive committee, G. E. Gustav Kuechle, David Vance, J. W. P. Lombard; visiting committee, Christian Wahl, John F. Burnham, Miss Lillian Wall, Mrs. Anna L. Wall, Dr. Ernest Copeland.

SOUTHERN STATES.

Kentucky State Medical Society.—The forty-sixth annual session of the Kentucky State Medical Society will be held in Louisville, May 22, 23, 24, 1901.

The Texas Medical Gazette.—The *Texas Medical Gazette* made its appearance in January of the present year. It is printed at Fort Worth, and edited by Drs. F. D. Thompson, Bacon Saunders, Frank Gray and W. R. Thompson.

Tri-State Medical Society.—At the recent meeting held at Richmond, Va., Dr. J. N. Upsher, of Richmond, Va., was elected president, and Dr. W. B. Royston, of Charlotte, N. C., secretary. The next meeting will be held at Asheville, N. C., February, 1902.

President of Johns Hopkins Resigns.—Dr. Daniel Coit Gilman, president of the Johns Hopkins University, Baltimore, has resigned, the resignation to go into effect at the close of the academic year, September 1st. Dr. Gilman has been with the university since its foundation, twenty-five years ago.

Conference on National Legislation.—The second annual conference on national legislation of the American Medical Association and its affiliated societies was held in Washington on February 20 and 21.

There were present delegates from Kentucky, Michigan, New York, Minnesota, Connecticut, West Virginia, Ohio, Arkansas, Wisconsin, North Dakota, District of Columbia, Washington, Pennsylvania, Maryland, Texas, U. S. Army, and U. S. Marine-Hospital Service.

The chairman, Dr. H. L. E. Johnson and the sub-committee appointed at the last conference to act for the conference during the interim of meetings, reported the results of their endeavors to carry out the wishes of the conference. The report showed that the efforts made to prevent the passage of the so-called "Antivivisection Bill" had been efficacious. The bill providing for the protection of the Florida coast from fishing boats which landed yellow fever suspects, and which was advocated by the conference, would, it was said, probably be passed at this session of Congress. The Army Reorganization Bill, which had recently become a law, did not, however, contain the provisions which the conference had desired for the enlargement and betterment of the Army Medical Corps. The protest against changes in this portion of the Bill as originally suggested by the Army Medical Department had been unavailing. A discussion on this subject showed, however, that the law as enacted did no injustice to the present members of the Army Medical Corps, and was not as unsatisfactory to the medical profession as it at first seemed. It was thought probable that Congress in the future might be induced to give further consideration to the subject, which would result in a betterment in the direction desired.

The conference was notified that one of the provisions of the Post Office Bill now before Congress would compel publishers to affix stamps to weekly medical journals to be delivered in large cities. A resolution was adopted to have a committee of the Conference protest at once to the proper committee of the Senate against the passage of this portion of the Act, which had already passed the House of Representatives.

A subcommittee was appointed to consider the whole subject of medical legislation and medical education in order to obviate the present inconvenience of compelling a physician who moves from one State to another to pass an examination for license, though a licensed practitioner.

The importance of having every State medical society represented in the Conference was recognized, and steps were taken to call the attention of unrepresented State societies to the necessity of action in this regard.

CANADA.

Postgraduate Course.—The corporation of McGill University at the suggestion of the medical faculty will establish a new postgraduate course in legal medicine.

MISCELLANY.

Marine Hospital Inquiry.—Marine Hospital Service has issued a letter of inquiry regarding influenza or grip, with a view to gathering and promulgating some correct information regarding its prevalence and types.

The Stylus.—*The Stylus* has been consolidated with the *Interstate Medical Journal* and the two publications continued under the latter name. Dr. William Porter, formerly editor of *The Stylus*, will be associated with Drs. W. B. Outten, R. B. H. Gradwohl and O. F. Ball, in the editorial management of the *Interstate Medical Journal*, St. Louis, Mo.

Headless Cigars.—Headless cigars are recommended, because they do away with the danger from the pasted end, with its possibilities for infection. Many factory operators are said to have the habit of moistening the fingers in the mouth before making the end twist. The discovery by the San Francisco Board of Health of tubercle bacilli in cigars emphasizes the danger.—*Public Health Journal*.

Obituary.—DR. S. J. SMITH, at Winchester, Va., on February 26, aged 73 years.—DR. D. W. SCOTT, at Oklahoma City, Okla., on February 27.—DR. W. F. Aiken, at Savannah, Ga., on February 27.—DR. OLIVER H. MCKITTRICK, at Washington, Ind., on February 28, aged 61 years.—DR. DITTENHOEFER, at San Francisco, Cal., on February 22, aged 40 years.—DR. GEORGE A. HAMIL, at Martinsburg, W. Va., on February 28.—DR. E. P. FRASER, at Los Angeles, Cal., on February 25, aged 66 years.—DR. EDWARD A. FESSENDEN, at Portland, Me., on February 28, aged 55 years.—DR. JOHN HALLER, at Rose Hill, Mo., on February 28.—DR. WILLIAM H. GATES, at Cleveland, Ohio, on March 4.—DR. JOHN SYLCURCK, at Frederick, Md., on March 5, aged 25 years.—DR. ALOYSIUS X. WHITFORD, at Parkville, Md., on February 28.—DR. THOMAS RILEY, at North Adams, Mass., on March 4, aged 58 years.—DR. JOHN SHELTON, at Leroy, Ill. on March 3, aged 68 years.—DR. L. C. MORGENSTERN, at Brooklyn, N. Y., on February 28, aged 37 years.

Changes in the Medical Corps of the U. S. Navy, for the week ended March 2, 1901:

PICKERELL, G., surgeon, detached from the Cavite Naval Station and ordered to the Mare Island Navy Yard.
THOMPSON, J. C., assistant surgeon, detached from the "Solace," and ordered home to wait orders.
WENTWORTH, A. R., surgeon, detached from the "Independence," and ordered to the "Solace."
CORDERIO, F. J. B., surgeon, detached from the "New Orleans," and ordered home via the "Buffalo."
STOKES, C. F., surgeon, detached from the "Buffalo" and ordered to the "New Orleans."
ROGERS, F., medical inspector, detached from recruiting duty, and ordered to the Asiatic Station for duty as fleet surgeon, sailing from San Francisco, March 15.
PERSONS, R. C., medical inspector, detached from duty as fleet surgeon, Asiatic Station, and ordered home to wait orders.
RUSH, W. H., surgeon, retired, detached from the Pensacola Navy Yard, and ordered home.

Changes in the U. S. Marine-Hospital Service, for the week ended February 28, 1901:

PURVIANCE, GEORGE, surgeon, granted leave of absence for 1 day, February 18.
DECKHAM, C. T., surgeon, granted leave of absence for 20 days from February 17, on account of sickness, February 19.
NYDEGGER, J. A., passed assistant surgeon, upon expiration of present leave of absence to report at Washington, D. C., for orders, February 12. To proceed to Cape Charles Quarantine, as inspector, February 15.
WICKES, H. W., passed assistant surgeon, granted leave of absence for 30 days from March 11, February 26.

TROTTER, F. E., assistant surgeon, upon being relieved by Assistant Surgeon T. D. Berry to proceed to Havana, Cuba, and report to the chief quarantine officer for duty, February 13.
BERRY, T. D., assistant surgeon, relieved from duty at Havana, and directed to proceed to Cienfuegos, Cuba, relieving Assistant Surgeon F. E. Trotter, February 18.
HARRIS, B. Y., acting assistant surgeon, granted leave of absence for 10 days, February 23.
MARSH, W. H., acting assistant surgeon, granted leave of absence for 4 days from February 27, February 26.

Health Reports.—The following cases of smallpox, yellow fever and plague, have been reported to the Surgeon-General U. S. Marine-Hospital Service, during the week ended March 2, 1901:

SMALLPOX—UNITED STATES.

1.—Chapman publishes a tracing from a case of **aortic regurgitation** that he believes furnishes proof of the pulse delay and of its modification in aortic regurgitation. He believes that this pulse delay is accounted for by a lengthened ventricular systole in fully compensated cases of aortic regurgitation. In making the tracing the author used Dr. Augustus Waller's digital sphygmograph. The normal heart-radial delay is about 0.18 second and the delay from the radial to the index pulse is, at the very most, 0.02 second. Allowing for errors in making measurements involving hundredths of a second, the patient had a **heart-index delay** of about $\frac{1}{10}$ second, which was probably indistinguishable by touch. Later the heart-index delay was 0.185 second. In the former case the blood-pressure was equal to 16 mm. of mercury; in the latter instance it was 20 mm. of mercury. The pulse-wave produced in cases of aortic regurgitation is slow, and this, the author believes, is the principal phenomenon in pulse delay. When delay is observed in these cases increased arterial tension tends to obliterate the delay; while diminished arterial tension makes it still more manifest. As compensation is attained the arteries are better filled, giving to the patient a corresponding sense of comfort and well-being and then the pulse-wave is accelerated. We see, then, that the attainment of a normal heart-radial delay is some measure of the correctness of the compensation and this may guide us to avoid further interference. [J.M.S.]

2.—The most important factor in the production of breathlessness is the saturation of the blood with carbon dioxide. The respiratory need is in proportion to the quantity of CO_2 in the blood, and in athletic exercise the quantity is rapidly increased by increased production. If muscular work in a given time is so great as to produce a quantity of CO_2 greater than the lungs are able to eliminate, the gas must accumulate in the system and the respiratory distress will increase progressively. Further, CO_2 has a weakening influence on muscle fiber and causes its contraction to be less effective. **Severe muscular exercise**, either **sudden or prolonged**, throws a great strain on the air-vesicles, leading to that which may be described as physiologic emphysema. In the case of a young university athlete the signs of this physiologic emphysema are: (1) Absence of apex-beat while at rest; (2) absence of superficial cardiac dulness; and (3) a hyperresonant percussion-note above the clavicles and at the edges of the sternum. If the muscular effort is persisted in, this physiologic emphysema may become pathologic. Again, this severe muscular exertion throws a great strain on the right side of the heart, and this danger is a very real one in **adolescents**. In the cases of two long-distance runners, exertion produced a systolic murmur in the right side of the heart from overdistention of the ventricle. There is a form of heart-strain in girls and young women, especially in those who do much stairclimbing, that is of the same nature, the symptoms of which disappear

when the patients are required to rest in the horizontal position. As Allbutt has pointed out, oft repeated muscular effort produces hypertrophy of the left ventricle, and the increased force with which the blood is thrown into the aorta causes that vessel to lose much of its elasticity, to become dilated, and finally causes the aortic valves to become incompetent. A symptom of these changes, which are of very gradual establishment, is sleeplessness. In order to prevent these dangers, all boys should be submitted to medical inspection before being allowed to compete in school sports, and the badly developed subjects should not be permitted to take part. Boys who are obviously growing with exceptional rapidity should be advised to avoid exercise requiring great muscular exertion. Healthy and strong boys who are in athletics should be examined once or twice a year as a safeguard against overstrain. Severe muscular exertion undoubtedly causes intermittent albuminuria. [J.M.S.]

3.—Smith gives the history of a case of **general paralysis** in a woman, 28 years of age, in whom there was undoubtedly **inherited syphilitic taint** and a history of paternal general paralysis. The case was referred to by Mott in the Croonian Lectures, in June, 1900. He also gives the history of a married woman, aged 24 years, who broke down with general paralysis. There was a history of paternal syphilis and general paralysis, although there were none of the ordinary signs of congenital syphilis in the patient herself and she had never acquired syphilis. In neither case was there any history of alcoholism or of sexual excess. There was no history of head injury nor of special stress or worry in either patient. Such cases seem to confirm Mott's opinion that some cases of general paralysis in which there is no history of acquired syphilis and in which the patient can no longer be classed as "juvenile" may owe their inception to inherited syphilis. [J.M.S.]

4.—After careful investigation, covering a period of 15 years, with the mortality from **pulmonary tuberculosis** in the Isle of Man, Davies finds that the results obtained can in no way be considered to support the theory that **strong winds** are accountable for the peculiar distribution of the disease in that locality. [J.M.S.]

5.—Smith reports a case of widespread carcinoma in a woman, aged 44 years, in whom **thyroid extract**, in 5-grain doses varying from two to four times daily, given for 6 months, produced great amelioration of the symptoms. The symptoms returned, however, in spite of persistence of the treatment. In the case of a child, aged 3 years, who first presented an eruption that simulated that of measles and which was soon cured; but in whom the eruption reappeared at varying intervals and became edematous, bullous, erythematous, and hemorrhagic, the administration of thyroid extract was followed by complete cure. In the case of a man, aged 50 years, who was suffering from chronic nephritis and who was becoming very fat, thyroid extract was beneficial in reducing the weight. [J.M.S.]

6.—Barr and Nicoll report a very interesting case of **cerebellar abscess** resulting from middle-ear disease after the mastoid operation had been performed. The abscess was drained through an opening made in the floor of the posterior fossa. The patient, whose condition was very bad at the time of the operation, greatly improved afterwards excepting that the abscess cavity did not seem to drain well. A second operation for the purpose of establishing through-and-through drainage was then thought advisable and an opening was made through the mastoid and petrous portions of the temporal bone and counter-drainage obtained in this way. The patient made an excellent recovery and two and a half years after operation showed no effect of his trouble save deafness on the affected side. Facial palsy, which was well marked before the operation, entirely disappeared soon afterward. [J.H.G.]

7.—McCurdy reports a case of fracture of the skull in the frontal region which was not recognized at the time of its occurrence, but 18 days afterwards the patient developed an epileptiform fit and three days later another. Operation was decided upon and when a button of bone was removed at the seat of fracture it was found that there was a considerable collection of pus between the dura and the skull. This was evacuated and the patient recovered well from the operation. At first there was considerable drainage, but four days after the operation he became irritable, complained of pain in the head and on the fifth day became unconscious. The

wound was again opened and the frontal lobe of the brain thoroughly explored for pus but none found. The patient died and at the necropsy it was found that the pus had extended downward and backward into the neighborhood of the Sylvian fissure. [J. H. G.]

8.—Ten men who were engaged in manufacturing zinc chlorid from crude zinc oxid and hydrochloric acid were **poisoned by arsenetted hydrogen**. Both the hydrochloric acid and the zinc oxid were known to contain arsenic, but the exact percentage was not determined. The symptoms were nausea, hot, burning pain from throat to stomach, intense thirst, violent vomiting, severe diarrhea, hemoglobinuria, jaundice of an intense coppery hue, prostration, cyanosis, and thready pulse. These symptoms gradually diminished after several days, and the feeling of depression, anemia, and pale-green color of the skin lasted for several weeks longer, and the man who was most severely affected and recovered, was unable to go to work for 5 weeks. One case terminated fatally. [J. M. S.]

9.—Smith found a yellow deposit that looked and smelled like sulphur on the skin of many patients who had been treated with electricity passed through Beckwith Harrogate water at a temperature of 99° F. The water contains a large amount of alkaline carbonates and a considerable amount of sodium sulphid. Two patients, particularly, who presented this deposit recovered, one from gouty eczema, rapidly. It would seem then from these clinical results, as well as from the results of electrolytic experiments, that nascent sulphur is deposited in the Harrogate sulphur water by electricity at the positive pole. In addition to the remedial influence of nascent sulphur, electricity stimulates the peripheral nerves all over the body in a sulphur bath and thus renders the action of sulphur more rapid and more efficacious in skin and gouty affections. [J. M. S.]

1.—Macnamara delivered the Hunterian oration, taking as his subject **craniology** and reviewed the labors of Hunter and the other able scientific men who followed him in that line of study, including the chief of England's craniologists Thurnam and Barnard Davis, who have made magnificent collections of prehistoric and other skulls. He remarks that we have now come to know that the size and form of the skull depends to a large extent on the growth of the bones of which it is formed along the lines of the various cranial sutures. It is well known that the frontal bone, which forms the vault of the anterior part of the cranium in the young of man and apes, is divided by a suture, and so long as this line of growth, together with the coronal and other sutures by which the frontal is separated from surrounding bones, remains open, the fore part of the skull and with it the anterior fossæ which it encloses can expand. But if the frontal and other anterior sutures of the cranium consolidate early in life the fore part of the skull cannot increase in capacity beyond the size it had reached in in-

fancy. Deneker has shown that in consequence of the early closure of the anterior sutures of the skull of anthropoid apes the fore part of their brain does not increase beyond the size it had attained at the end of the first year of life, but in man these sutures do not consolidate until a much later period, so that the anterior lobes of his brain are enabled to become far more perfectly developed than the correspondent lobes among apes. Men of the same bulk have 4 times as much superficial brain-surface as anthropoid apes. Whatever functions the anterior lobes of the brain perform, their cortical nerve elements in conjunction with those of the other lobes of the brain control to a large extent our higher intellectual faculties. If we compare the skull of an Englishman with that of one of the natives of Australia a wide difference may be noted between the development of their frontal regions and also as the nature of the sections of many of their skulls. Schwabe has arrived at the conclusion that the Java skull, taking its capacity and form into consideration, is on the border line between that of man and anthropoid apes. Until the Java skull was found, the earliest known human skulls had a cranial capacity of about 1220 cu.cm. The postorbital index or narrowing of the Java skull is 19.3, as compared with the average of living Europeans, which is 12. The anterior surface of the lower jaw among the existing races of Europe projects to form the chin. Among apes the reverse is the case, for the anterior surface of their mandibles recedes. [W. A. N. D.]

2.—In his second lecture on the surgery of pregnancy and of labor complicated with tumors, Bland-Sutton treats of the coexistence of pregnancy and fibroids, and presents illustrative cases of this complication. He remarks that the impaction of the uterus with fibroids secondary to conception is not only responsible for pain, and in a certain proportion of cases to retention of urine from direct pressure on the urethra, but it probably accounts for the frequency with which abortion occurs under these conditions, and it is interesting to observe how even a relatively small fibroid will impede the ascension of the uterus as it enlarges during pregnancy and gives rise to much trouble. The tumor may likewise obstruct delivery when the pregnancy grows to full term. Septic endometritis is rendered more serious when the infected uterus contains fibroids. Necrosis and consequent gangrene of the fibroid arises usually from injury, and may even result from the efforts of the uterus itself to expel the pedunculated tumor. It does not necessarily follow that in every parturient woman with a fibroid the tumor becomes septic. In cases complicated by tumor which have reached term, if the growth cannot be pushed out of the pelvis, cesarean section should be performed. [W. A. N. D.]

3.—Klein, in an article entitled **Remarks on agglutination by plague blood**, states that unfortunately the plague bacilli show a tendency to adhere together in broth cultures which vitiates the agglutination test when this media is employed. In the cultures upon agar, glycerin agar or serum the plague bacilli produce a sticky, intercellular substance. After a number of attempts at securing a good emulsion of the plague bacilli, the author finally tried the following: The growth upon gelatin (which is somewhat drier than the growth upon other artificial culture media) was mixed with a physiological salt-solution. This solution has the property of dissolving globulin. With this method a uniform distribution of the bacilli was brought about. The author found that by adding bouillon in the proportion of 1 to 20 (of the emulsion) agglutination took place in from 12 to 20 minutes. Even with the dilution of 1 to 40 this occurred. This demonstrates the uselessness of the agglutination test when using a bouillon culture of plague bacilli. Normal human blood and normal mouse's blood mixed in the proportion of 1 part of blood to 20 parts of emulsion failed to give the agglutination test even after 24 hours. He next injected rats with Haffkine's prophylactic and then with living plague cultures. In all the animals slight bubo formation was noted and a general illness was produced, but recovery followed. After 2 or 3 weeks the blood of these rats was tested, and agglutination was present. The author concludes by saying that the agglutination test is positive with the blood of an animal convalescent from plague, but from his own experience he cannot make the same statement in regard to the blood of a human individual convalescing from this disease. [F. J. K.]

4.—Wherry discusses the subject of **asymmetry** in both upper and lower extremities in the lower animals as well as in man. He argues that by proper exercise of a short limb its growth can be encouraged and oftentimes its length increased. He thinks it is a mistake to simply put a high-heeled shoe on a short limb and allow the patient to go through youth without any attempt being made to develop the part. [J.H.G.]

5.—Fawcett and Pakes report an interesting case of **subacute glanders** occurring in a man, 45 years of age, in whom the clinical symptoms were not very marked but the bacteriological examination positive. The patient had a number of subcutaneous swellings, a few small furuncles, a small abscess in the left forearm, and fluid in the knee joint. There were no typical ulcers of the skin, no bullous or pustular eruptions, no rhinorrhea, and no intramuscular abscesses. The patient died and postmortem the heart, blood, spleen, and fluid of the knee-joint gave cultures of the bacillus mallei. The culture injected in a guineapig produced the disease. [J.H.G.]

6.—Thursfield reports **17 cases of posterior basic meningitis** which occurred between the period of July, 1899, to August, 1900, in the medical wards at Great Ormond Street. In 12 the diagnosis was confirmed by autopsy. Two cases were not examined after death, one was transferred from the wards during the course of the disease on account of intercurrent diphtheria, and 2 cases recovered. The bacteriological examination in nine instances showed that in 8 of these an intracellular diplococcus was present in the exudate. In 5 cases inoculations were made upon artificial media, 6 giving rise to a distinct growth which was, however, always of low vitality. In 1 of the cultures a mixed infection was found. The principal clinical features were the following: Seven of the cases occurred in females, 10 in males. The average age was 9 months, excluding 4 cases which occurred in their fourth year and over. In the latter cases there was some difficulty in making a diagnosis. The onset of the disease was marked by retraction of the head in 3 cases, vomiting in 9, convulsions in 4, and bulging of the fontanels in 6 cases. Sooner or later retraction of the head appeared in all of the cases. This is considered one of the cardinal symptoms. The author next mentions a case of retraction of the head which at the autopsy did not show signs of meningitis. Of the ocular symptoms he frequently noted early strabismus and nystagmus. In 13 out of the 17 cases changes in the fundus were observed, and amaurosis was seen in 7 cases. Retraction of the upper lid, which occurred in 7 instances, is regarded as the most constant and characteristic ocular symptom of posterior basic meningitis. Vomiting and rapid progressive emaciation were present in all of the cases. The other remaining symptoms are those common to other forms of meningitis. He mentions that a clinical feature, sometimes present in posterior meningitis, is hydrocephalus, and involvement of the joints. The sudden onset, the head retraction, the rapid emaciation and the chronic course render the diagnosis easy as a rule. Leukocytosis was found in the more acute form, while in the chronic variety the number of leukocytes was normal. Lumbar puncture was performed once for diagnostic purposes. The treatment that was instituted he believes was ineffective. In conclusion he mentions that there are a number of clinical varieties of this disease, the variation depending largely upon the age of the patient and the virulence of the toxin. [F.J.K.]

7.—Fenwick thinks that **sarcoma of the stomach** is much more frequent than is commonly supposed and that it is frequently mistaken for carcinoma. He thinks that it constitutes probably from 5 to 8% of all primary neoplasms of the stomach. The round-cell sarcoma is the most frequently seen variety occurring in the stomach and the spindle-cell or fibro-sarcoma is next in frequency; these latter growths sometimes reach an enormous size and are not infrequently pedunculated. Myosarcomata are rare in the stomach, but they frequently reach enormous size and sometimes undergo cystic degeneration. Angiosarcoma is very rare indeed. All varieties of sarcomata are apt to have secondary growths arising in organs more or less remote from the primary disease. Sarcomatous nodules are frequently present in the skin of the abdomen. In almost all cases the lymphatic glands of the stomach are enlarged and sometimes the retroperitoneal, mesenteric, and mediastinal glands are

enlarged. The elongated nodular epigastric tumor so frequently seen in carcinoma of the stomach and due to the involvement of the omentum is absent in sarcoma of the stomach. In about 15% of the cases of round cell sarcoma the spleen is considerably enlarged. Perforation of the stomach is much more frequent in sarcoma than in carcinoma. The two conditions have twice been found associated. Leukocytosis is not infrequently present in cases of sarcoma of the stomach. Diarrhea is a noticeable feature in the round cell type. Hematemesis is not often a prominent symptom in round-cell sarcoma. The Oppler-Bas bacillus has been demonstrated in these cases. Unless the pylorus is involved death usually occurs from exhaustion, though sometimes from perforation and peritonitis. The formation of a perigastric abscess is rare because adhesions are not apt to form before perforation takes place. In many cases of sarcoma of the stomach there is a slight but continuous pyrexia. [J.H.G.]

8.—Elison reports the case of a man who presented himself with a foreign body protruding from the abdomen and which on removal proved to be a portion of a hemostatic forceps. This had been left in the patient's abdomen after an operation done 8 years before. [J.H.G.]

9.—Borland describes a case of **cephalhematoma** in which there was no elevation of temperature, no dyspnea, and no cerebral complications. There was also no history of hemophilia. [W.A.N.D.]

10.—Rolleston reports a case of **primary carcinoma of the ampulla of Vater**. The patient was a man, 66 years of age, and was admitted to the hospital deeply jaundiced, with an enlarged liver and gallbladder, and with some tenderness over these organs, but no abdominal distention or ascites. The urine contained albumin and bile but no sugar. On the fourth day after admission the patient suddenly went into a collapse and died within 18 hours. At the necropsy it was found that the duct formed by the union of the common bile duct and the duct of the pancreas was the seat of a carcinoma completely obstructing its caliber. The hepatic cystic ducts and the gallbladder were greatly distended and the liver enlarged. There was a large cystic dilation of the pancreatic duct which contained recent blood-clot. Rolleston thinks that the cause of death in this case was acute pancreatitis with hemorrhage. [J.H.G.]

11.—Jordan recommends the use of a solution of **formalin and glycerin**, the strength of the formalin varying from 1% to 4%, and he adds that the solution should always be freshly prepared. It is recommended (1) in throat affections, such as tonsillitis, diphtheria, and for the erythematous sore throat of scarlet fever; (2) as a mouth wash in various forms of stomatitis; (3) in parasitic affections of the skin such as tinea tonsurans; and (4) as a urethral injection. The author cured a case of acute gonorrhea by a 1% formalin glycerin solution. He is not prepared to advise its general use as a urethral injection on account of the pain and swelling of the mucous membrane which follows its application.

12.—Wilson states his belief in the possibility of the condition of the mother mentally and otherwise affecting the fetus in utero, and gives an interesting illustration of **maternal impressions** in lower life, the deformity occurring in a bush-buck ewe (*Tragelaphus sylvaticus*). [W.A.N.D.]

14.—Coates gives a report of an **outbreak of typhus fever** in Manchester. The Health Officer of Manchester was informed, on January 8, of the illness of 7 women and a boy, who were employed in a rag sorting establishment. It was found that the disease was typhus fever. In this establishment 14 women were employed, working in two rooms. In one room woolen rags were sorted, while in the other cotton rags. Of those stricken with the disease all had handled the woolen rags and no case developed in those who handled the cotton material. The disease in the eight occurred between the 20th and 24th of December. The sudden onset was marked by chills, pain in the back and limbs, headache, and in some vomiting. In 3 a measles rash developed. In 5 who recovered the illness terminated by crisis. The infection seemed to spread from this focus. Up to January 10, 33 cases with 8 deaths were reported. On February 1 a case was reported, the infection of which was traced to June, 1900. The total number of cases from June to February 1 was 53. The management of the outbreak consisted in removing the patients to the Hospital for Infectious Dis-

eases, disinfection of the infected houses, isolation of those who came in contact with the sick for two weeks, house-to-house inspection, dirty and filthy quarters were disinfected, and the rag-sorting establishment from which the epidemic probably originated was also disinfected. [T.L.C.]

New York Medical Journal.

1. The Axis-traction Forceps, with Special Reference to Rotary Axis-traction in the Treatment of Posterior Positions of the Anatomical Head. SIMON MARX.
2. Metrorrhagia Due to Inflammatory Processes Within the Pelvis. EDWIN B. CRAGIN.
3. The Pathology of Intrauterine Death. NEIL MACPHATTER.
4. The Electrochemical Action of the X-Rays in Tuberculosis. J. RUDIS JICINSKY.
5. The Palliative Operative Treatment of Carcinoma of the Posterior Wall of the Stomach. ALBERT VANDER-VEER.
6. Cancer of the Uterus. ANDREW F. CURRIER.
7. Hemorrhage from a Circumtonsillar Abscess. WALTER F. CHAPPELL.

1.—Simon Marx makes a plea for more recognition and more frequent employment of the **axis-traction forceps**. In his experience he has found the axis-traction forceps of Tarnier to be of great value where posterior positions of the head present. The length of the forceps which render sterilization difficult is one of the objections, but according to the author, this can be obviated by using a baby's bath-tub as a sterilizer. In unskillful hands there is more danger of slipping than with the ordinary forceps. The danger of disfigurement can be overcome by entirely dispensing with the fixation screw. It having been shown that the blades are kept in place by the pelvic structures and the impact from the fetal head, the screw can be discarded. When employing the Tarnier forceps, unlike with ordinary forceps, influence upon moulding, rotation and descent of the head does not have to be exerted by a purchase upon the handles, and by traction and pressure on the head; the handles of the forceps are not interfered with, and are simply employed as an index of the position of the head and as an indication in which direction traction is to be made. The force of extraction being directly exercised upon the cross-bar attached to the traction rods, rotation can then occur. In employing ordinary forceps to the head, the more powerful the extraction force the greater the compression upon the skull; this is overcome in the axis-traction forceps where extraction is applied to and from the cross-bar. The saving of exertion on the part of the operator, according to the author, is the greatest advantage possessed by the Tarnier forceps. The handles of the instrument must be taken as a guide as to the direction of traction, no matter what their position, otherwise pulling directly backward as is done in employing the ordinary instruments may cause an improper leverage, and the forceps may be directly pulled off. The author has given the name **rotary axis-traction** to a procedure which combines axis-traction and artificial rotation. He states that as rotation in the majority of cases occurs at the pelvic floor, he has frequently, in occiput posterior positions, succeeded in rotating the head anteriorly by making axis-traction, and relying upon the resistance of the pelvic structures and that afforded by the ischial spines. The Tarnier forceps by their free mobility rotate with the head and nature can thus be assisted by rotary axis-traction. He preferably applies the blades so that they are in one of the oblique diameters of the pelvis. Traction is made with the right hand and with the left by gentle rotation, the forceps are influenced to turn in the direction of the presenting part. The author refers to one of his previous articles in which he quotes the following: "To my mind, there are no instruments that we are called upon to use which are more, if I might say, intelligent than these. They are strength-saving to the accoucheur, safe for the mother, and eminently more safe for the child. Whilst they have much, very much, in their favor, yet there are certain objections to their use which, in a great measure, cannot be overcome, and these objections do not all hold good, since they apply with equal force to the ordinary obstetric forceps." [M.R.D.]

2.—Cragin remarks that in the discussion of the etiology of **metrorrhagia** due to inflammatory processes within the pelvis, three factors must be considered: (1) The endometrium; (2) the muscular wall of the uterus; (3) the blood-vessels of the uterus. Hemorrhage is so slight in amount during an acute endometritis that this disease may be dismissed as a common cause of metrorrhagia. With chronic endometritis, however, metrorrhagia is commonly associated, and in this condition the endometrium is rough and hypertrophied. The two conditions most commonly interfering with the normal contractions of the uterine muscle in the nonpregnant state are: (1) Tumors of the uterine wall; (2) chronic interstitial inflammation of the uterine wall in which there is atrophy of the muscular tissue and an increase of new connective tissue. Although both of these conditions most often produce metrorrhagia through the medium of a chronic endometritis, occasionally the endometrium seems but slightly involved and the bleeding appears to be caused by a lack of sufficient elasticity in the uterine muscle, due to interference with the normal muscular contraction. Interference with the normal contraction of the arteries themselves favors the development of metrorrhagia. Thus, a condition of arterial sclerosis occasionally is noted at or near the time of the menopause, which results in an insufficient elasticity of the vessels either to maintain the normal balance of uterine circulation or to check the flow beginning at the menstrual period. Consequently, a metrorrhagia will be produced. If the bleeding be associated with an absence of hypertrophied endometrium, or if it persist after repeated curettage, hysterectomy may be justified. [W.A.N.D.]

3.—To be abstracted when article is completed.

4.—J. Rudis-Jicinsky discusses the **electrochemical action of the x-rays in tuberculosis**. The application of the x-ray to early cases of tuberculosis is highly recommended by certain authorities. The author has found in certain early cases of the disease, on x-ray examination, a slight haziness, indicating the beginning of tuberculous infiltration in the apices. He has not only attacked the seat of the disease by x-ray treatment, but has placed his patients in pure air, at suitable temperature, and in good hygienic surroundings. The exposure varies in these cases from 10 to 15 minutes at each sitting. The rays are to be observed with the fluoroscope at each exposure, the tube tested to see that it is working at its best, and the apparatus must be under full control of the expert, who, with the help of the x-ray, is enabled to determine the limitations of the diseased portion of the lung. His results have been most encouraging, and he urges that this method of treatment should receive more attention in all curable cases. [T.L.C.]

5.—Albert Vander Veer reports **four cases in which the palliative operative treatment of carcinoma of the posterior wall of the stomach was performed**. From these cases he summarizes as follows: Continued gastric disturbances that do not yield to medical treatment should undergo careful examination as to the possibility of malignancy being present. Even in cases where a positive diagnosis of malignancy is not made, and the patient continues to emaciate and the suffering increases, he advocates an exploratory incision, and if there is no malignant growth a **gastrointestinal anastomosis** should be made, as recommended by Dr. Weir. **Malignant growths in the posterior wall of the stomach** are more difficult to diagnose and sometimes escape the notice of the most careful diagnostician. When an exploratory incision has been made and a malignant growth is found in the posterior walls of the stomach, with no possibility of removal, by resection or otherwise, although quite deep, yet he believes that the patient should submit to a **gastrointestinal anastomosis**. Finally he recommends that the blood of such patients should be examined most carefully. [T.L.C.]

7.—Walter F. Chappell reports a case of **hemorrhage from a circumtonsillar abscess**. Chappell finds 10 cases reported in the literature with 2 recoveries. His own case recovered. He believes that the spontaneous rupture of the tonsillar abscess in all these cases is very suggestive, and expresses the opinion that an early incision would have prevented the extensive ulceration which implicated one of the large vessels. **Immediate ligation of the carotid** on the occurrence of the first hemorrhage should be practised, or a **free incision** through the

anterior wall of the soft palate and firm packing of the abscess with antiseptic gauze. The latter method was followed successfully in his case. [T.L.C.]

Medical Record.

1. The Treatment of Rheumatic and Allied Diseases of Joints Complicated by Deformity. VIRGIL P. GIBNEY.
2. An Improved Method of Examining the Female Bladder, Admitting Intravesical Operations and Treatment of the Ureters. WILLIAM R. PRYOR.
3. Some Facts Regarding "Ureine." A. F. CHACE and WILLIAM J. GIES.
4. A Method of Reducing Dislocations of the Thumb. JOHN F. ERDMANN.
5. Tuberculosis in Prisons and Reformatories. S. A. KNOFF.

1.—Gibney of New York reports 22 cases of **rheumatic and allied diseases of joints complicated by deformity**. He states that his experience with the **hot-air treatment in multiple arthritis with deformity** has been disappointing. There is usually a temporary relief, but relapses occur in which the deformity must be corrected under an anesthetic, and prolonged use of plaster of Paris. In conclusion, Gibney states that it is difficult to fix upon any one form of treatment that has yielded the best result, but he commends the **forcible breaking up of adhesions** when inflammatory conditions have subsided, the frequent recurrence to these operations and the discriminate use of plaster of Paris. Each year his belief grows stronger in the efficiency of **absolute immobilization as a promoter of absorption of chronic inflammatory products**. He commends also the **protection of joints with a limited range of motion by apparatus within the bounds of this motion**. Recently he has attempted the correction of deformity in a rigid spine by extension with moderate force, and his result up to this writing is gratifying. The apparatus employed is that used in the correction of the bones in the deformity of Pott's disease and is employed without an anesthetic. [T.L.C.]

2.—William R. Pryor presents an improved method of examining the female bladder, admitting intravesical operations and treatment of the ureter. His **cystoscope** consists of a main tube for inspection, alongside of which is attached a smaller tube for carrying a lamp and the stand which holds it. The tube for illumination extends beyond the tube for inspection and consequently the rays of light project beyond and outside the tube for inspection, no rays entering the latter. The light illuminates 100° of the bladder circumference, 260° being in the shadow. The heat from the light is taken up from the metal of the tube, the lamp, lamp-holder, and wires are completely insulated, neither urine nor other fluids can short-circuit the current when this apparatus is connected. The advantages he claims for the instrument are a tube for inspection free from obstruction and free from light-rays, either direct or reflected; the absence of necessity for focussing rays of light which embarrass the operator in his maneuvers when a head-mirror or lamp is employed; the passage of the rays of light directly to the object to be inspected; and lastly, the perfect ease with which demonstrations can be made; absence of heat; absence of urine about the trigone; absence of the necessity for pumping out urine. The bladder assumes the shape of an open equilateral triangle with rounded corners. The advantage of this posture over the knee-chest is due chiefly to the straight lines which the vaginal segment (in which the ureteral orifices are found) and the pubic segment assume. He first examines the ureteral orifices and the trigonum, for there we find the most of the lesions. He then sweeps the instrument over the lateral vesical walls and by turning the handle down the light illuminated the pubic segment. In catheterizing the ureters for the purpose of securing separate specimens in ureteral and kidney lesions he has been able to secure sterile urine from both ureters even when an acute cystitis existed. He first detailed the objections to the ordinary methods of examination and then advocates placing the patient on her back in the lithotomy position. He dilates the ureter with a 30 or 36 (French) straight sound, but states that no dilatation is needed when

the smaller tube of the endoscope is used with cocain. He next proceeds to introduce the obdurator speculum and evacuates the urine. The table is then lowered to the requisite angle usually to about 45°. The uterus now sinks away from the pubis and drags with it that portion of the bladder which is covered by that portion of the peritoneum. [T.L.C.]

3.—A. F. Chace and William J. Gies present a comprehensive criticism of the recent paper by Dr. William Ovid Moor upon the **discovery of ureine**, the principal organic constituent of urine and the true cause of uremia. From the laboratory of physiological chemistry of Columbia University at the College of Physicians and Surgeons of New York. The fact has long been known that normal urine contains substances of a very toxic character. **Potassium compounds** are prominent among these, but more poisonous still are the various **organic bodies of an alkaloidal nature**, present in only minute proportions. These writers believe that Moor's method of preparing **ureine** fails to eliminate completely either **potassium salts** or the **normal basic alkaloidal bodies** giving the typical reactions with **potassium ferri-cyanid and ferric chlorid**, and the toxicity ascribed to **ureine** must be referred at least in part to these substances dissolved in it. Summing up they state: Ureine is not a chemical individual. It is a mixture containing several of the organic substances and a considerable proportion of inorganic salts ordinarily found in normal urine. Further, its toxicity can be referred to some of these normal urinary constituents. [T.L.C.]

4.—Erdmann reviews the various causes of **irreducible dislocations of the thumb** and suggests a method of reduction which he has never failed to find successful. It consists of manipulation and is free from all danger to the parts. The two thumbs of the operator are placed over the dislocated end of one of the bones and the forefinger over the other. By pressure the dislocation is reduced. The article is illustrated by photographs showing the method of reduction. [J.H.G.]

5.—S. A. Knopf discusses the subject of tuberculosis in prisons and reformatories. He believes the spread of infection should be prevented by separating the tuberculous prisoner from the nontuberculous in the workshop as well as the cell. He urges the necessity of careful physical examination of each prisoner on admission, which should include the bacteriological examination of the sputum, and advises that they should be reexamined every 3 months. This should not be confined to prisoners alone, but should be obligatory for wardens, keepers, officials, and help. He suggests the feasibility of forming convict camps, as has been done in Alabama, and advises the patients to be carefully instructed as to the danger in coughing and spitting upon the floors and corridors. He goes so far as to recommend that all tuberculous patients should be forced to wear mouth-masks. Hygienic surroundings must be provided. The author in conclusion wisely remarks that we must not overlook the fact that these tuberculous patients will, in many cases, soon be at liberty in their diseased state and act as agents for the spread of tuberculosis. [T.L.C.]

Medical News.

March 2, 1901. [Vol. lxxviii, No. 9.]

1. Veratrum Viride; Its Value in Some Conditions of Toxemia. A. B. ISHAM.
2. The Treatment of Delirium Tremens by the Intravenous Infusion of Saline Solution. JAMES P. WARBASSE.
3. Yohimbin and Its Salts; A New Aphrodisiac. ROBERTS BARTHOLOW.
4. Thymotal; A New Remedy for Ankylostomiasis. J. E. POOL.
5. Belladonna vs. Scopolia. REYNOLD WEBB WILCOX.
6. Immunization for Typhoid Fever; A Review. H. W. McLAUTHLIN.
7. Malarial Fever, with Special Reference to the Value of Blood Examinations; Report of Cases. HERBERT OLD.

1.—Isham reports the following cases in which **veratrum viride** was used with marked benefit: (1) Peritonitis; (2) uremia; (3) hepatic colic from passing of gallstones. The drug affects first the glandular system, including the sudo-

rikerous and salivary glands, although the latter are not so much affected if there is profuse sweating. The cells of the liver are undoubtedly excited to increased activity. The author thinks that activity of the salivary glands is much less important in toxemia than that of either the liver or sweat glands, although the organ may exercise a very considerable power in neutralizing and removing leukomaines and toxins. The liver is a factor in the conservation of life under conditions of toxemia which is of great importance. The retching and vomiting also indirectly spur up the liver to increased secretion, through muscular action and siphonage. The drug's action is thought to be due to the effect upon vasomotor functions and the exertion of some stimulating influence on the cells of the liver, salivary and sweat glands. [T.M.T.]

2.—According to Warbasse, treatment of delirium tremens by the intravenous infusion of saline solution accomplishes the following: 1. Increases the amount of the circulating medium in which the toxic materials are dissolved, thereby diluting the poison and bathing the nerve centers with a more attenuated solution of the same. 2. The amount of circulating fluid is increased above the normal, so that the excretion of fluids through all the fluid-excreting channels is increased, thereby carrying off in solution much of the contained toxins. 3. The action of the heart is improved by the filling of the relaxed vessels. These suffice to restore the physiological equilibrium and turn the balance in favor of recovery. [T.M.T.]

3.—Bartholow, in his experiments with yohimbin on animals indicates that it is a central paralyzer of mobility, but not of sensibility. With the muscular paresis occur spasms of the muscles and nodding movements of the head, involving the neck muscles. It affects respiration by action on the chest muscle and diaphragm. Heart action is weakened by it, and ultimately, the organ is paralyzed, stopping in diastole. The result is due not to peripheral impressions, but to an action of the cardiac motor ganglia. It is not a muscular poison; the muscles themselves react to mechanical and electrical excitation. Dose, 1/2 to 1 grain. [T.M.T.]

4.—Pool advises the substitution of thymotal for thymol in ankylostomiasis, based on the following reasons: (1) Because it is without odor, and can therefore be taken by children who cannot swallow pills. At the same time the danger of being suffocated by thymol electuary, which occasionally happens in infants, is avoided; (2) because it is not dissolved in the stomach, as is thymol, and is not vomited, as is often the case with thymol; (3) because thymotal does not cause giddiness, as thymol does very shortly after it is taken; (4) because the danger of thymol poisoning is reduced, especially to those children whose bodies are weakened by ankylostoma; (5) because the carbonate of thymol is broken up in the body by the influence of the bile and the mucus of the intestines, and thymol is formed exactly at the places where the ankylostomas are found in the body—i. e., duodenum and the adjacent parts of the intestines; (6) because it cures more rapidly than thymol. Dose: Adult, 30 grains; children, 15 grains; babies, 7.5 grains—3 to 4 times a day. Treatment kept up for 4 days, and on fifth day a purgative given. [T.M.T.]

6.—Dr. McLaughlin, in his article on immunization for typhoid fever, gives a detailed account of Wright's observations of typhoid among inoculated and uninoculated in the British Indian Army—period of observation, about nine months; total number of men under observation, 11,295; number inoculated, 2,835; number not inoculated, 8,460; number of cases of typhoid among inoculated, 27, or 0.95%; number of cases of typhoid among uninoculated, 213, or 2.5%; number of deaths from typhoid among inoculated, 5, or 0.2%; number of deaths from typhoid among uninoculated, 23, or 0.34%. [T.M.T.]

Boston Medical and Surgical Journal.

3. Two Cases of Ligature of the Internal Jugular Vein for Infective Thrombosis of the Sigmoid Sinus Due to Purulent Otitis Media; one Recovery and one Death. FREDERICK L. JANE.

2.—Avulsion of a finger is caused by firm holding of the finger in something moving away from the person or by holding of the finger while the hand is pulled away from it. The bones are usually separated through one of the joints. Avulsion of the terminal phalanx is the most common variety. A tendon, usually the deep flexor, is, as a rule, attached to the avulsed finger, and the tendon is most frequently pulled off at its exit from the muscle. The skin is usually pulled off at a higher point than that at which the bones give way. Hemorrhage is seldom troublesome. No attempt should be made to replace the avulsed portion of the finger. An accident of this kind to a baby, 20 months old, is reported. [J.M.S.]

3.—Jack reports 2 cases in which the internal jugular vein was ligated for infective thrombosis of the sigmoid sinus due to purulent otitis media. One of the patients died and one recovered. In acute cases, before ligating the vein, remove the purulent material in the sinus until a healthy clot is reached. After this operation, if rigors and elevation of temperature recur immediately, ligate the jugular vein and then remove the entire thrombus until there is a free flow of blood. If at the original operation no healthy clot is formed, ligate immediately. In chronic cases no time should be lost in ligating the vein and completely removing the thrombus. [J.M.S.]

2.—Dench thinks that wherever there is the slightest evidence of inflammation of the mastoid cells a thorough exploration should be made. If this is done in an aseptic manner the danger of the operation is practically nil. The incision should be made as close to the ear as possible. Exploration of the entire pneumatic structure, including the cells at the apex of the process, should be made. The mastoid antrum should be entered as the first step of the procedure. This avoids accidental exposure of the meninges or of the lateral sinus. He thinks that the wound heals as rapidly when it is packed as when it is partially sutured. [J.H.G.]

3.—Allport discusses at some length the different views held by the profession regarding the treatment of chronic otorrhea. The great difficulty in deciding upon the treatment of this condition depends upon an exact diagnosis of

the extent of the disease. Oftentimes the symptoms are very slight when the disease is very extensive, and the contrary is not infrequently true. Allport thinks that as soon as a diagnosis of extension to the mastoid has been made the radical operation should be done. If the aural discharge continues in spite of proper local treatment for a period of 3 months, accompanied by recurrent and persistent exuberant granulations and necrosis, the case assumes a decidedly suspicious aspect. This is especially true if the opening is in Shrapnell's membrane or in the posterior superior quadrant of the main membrane, and if carious bone is found in the upper and posterior wall of the tympanic cavity. Other indications for the posterior operation are a cheesy or flaky discharge, the presence of the streptococcus, influenza, or tubercle bacilli, and also the condition of the discharge after ossiculectomy and curettage. [J.H.G.]

4.—Gradle has met with 20 instances of artificial communicating passages between the meatus and the attic of the middle ear. This defect was usually a fissure in the external wall of the attic but in some instances it was a fistula. In a few cases the membrana tympani was totally gone. The patients were all adults and dated their trouble back to childhood. The origin of the condition is due to necrosis of bone. All of the patients were suffering from a chronic otorrhea. Nineteen of the twenty patients were cured without an operation, although a relapse was not infrequent. Gradle does not think that the treatment of chronic otitic suppuration is made more difficult by the presence of bony defects. [J.H.G.]

5.—Hinsdale reports a case of **aphasia with letter-blindness without word-blindness** in a patient, a physician 35 years of age. He was suffering from pulmonary tuberculosis and suddenly had an attack of paralysis involving the right side of the face, the right arm, and the right leg. The paralysis disappeared rapidly in the course of a few days. Speech was almost completely lost during the first 24 hours. The patient could only speak the word "No." Sensation was not disturbed and the kneejerks were normal. Some time after the patient could not name objects although he could recognize them (word-deafness). The patient also mispronounced some words, and incorrectly substituted words. During the patient's illness he regularly read the daily papers. When asked to read the alphabet, instead of saying "A," "B," "C," he would count "1," "2," "3," but when shown the words "boy" and "child" he pronounced them. He therefore had letter-blindness but not word-blindness. The aphasia persisted for nearly a year and a half. [F.J.K.]

6.—Brown, Langdon and Wolfstein report a case of **combined sclerosis of Lichtheim-Putnam-Dana** type accompanying pernicious anemia. The patient, 34 years of age, was the proprietor of a restaurant. Dr. Brown first saw the patient in July, 1899. He had complained of failing health for three or four years. After careful examination the diagnosis of pernicious anemia was made. The blood-count showed 1,279,440 erythrocytes, 3,600 leukocytes and 32% of hemoglobin; the color index was 1.3. Microscopical examination of the stain films disclosed a number of megaloblasts, a pronounced poikilocytosis and marked polychromatophilia. The patient was admitted to the Cincinnati Hospital in January, 1900, under the care of Dr. Langdon. He complained of stiffness and weakness in the legs and inability to walk. A blood count showed 1,661,805 red blood cells, 3,000 white blood cells, 54% of hemoglobin and a color index of 1.54. A differential count revealed an increase in the lymphocytes. Incoordination was apparent in the upper and lower extremities. He could not walk on account of weakness and rigidity, the knee-jerks were exaggerated and ankle-clonus and Babinski's sign were noted. There was some disturbance of sensation. Death occurred on April 11. The autopsy revealed no gross lesions of the organs. Microscopically the spinal cord exhibited degeneration in the posterior and in the lateral tracts. The degeneration in the posterior tracts commenced low down in the cord about the level of the lower lumbar and extended as high up as the pyramidal decussation. The pyramidal tract from the level of the olivary bodies showed downward degeneration, extending as far as the sacral region. The posterior nerve-root bundles were involved. Hyaline changes of the smaller bloodvessels were also noted, but no evidences of inflammation. Dr. Wolfstein and Dr. Langdon believe that the condi-

tion was a primary systemic degeneration dependent upon the pernicious anemia. [F.J.K.]

7.—Allen reviews the **treatment of croupous pneumonia**. He recommends the initial use of calomel and rhubarb, and during the course of the disease the bowels are to be kept open with castor-oil and turpentine. Sodium salicylate given in Phillip's milk of magnesia is given until the fourth to the sixth day of the disease. During the exacerbation of the fever Dover's powder is recommended. During the middle of the second stage of the disease the following stimulants are used: Digitalis, strophanthus, and strychnin. After the sixth day, instead of the sodium salicylate he gives tincture of the chlorid of iron, potassium iodid, quinin, and nitroglycerin. With good results he uses oxygen inhalations. [F.J.K.]

8.—**Irrigation of the colon** as a therapeutic measure is discussed by Lochboehler. The introduction of water into the bowel provokes expulsion of its contents, acts as a solvent for catarrhal product and when large quantities of fluid are used thermal changes and peristalsis are brought about. Irrigations may act mechanically and are sometimes indicated to relieve constriction of the bowel and incarcerated hernia. Irrigations are also recommended for such conditions as hemorrhage, cholera, yellow fever, diabetes, uremia, shock and collapse. Normal saline solution has been given with the best results, as it stimulates the nervous system, improves the circulation and restores the temperature to the normal. [F.J.K.]

9.—Brower makes a protest against the use of **proprietary remedies**. The author found that three leading dispensing druggists of Chicago, in examining the last 1,000 prescriptions on their files, respectively 20%, 21%, and 26% of the prescriptions called for proprietary remedies. The author sees no reason why physicians should not prescribe liquor chloralis et potassi bromidi compositus instead of prescribing "bromidia," and pulvis acetanilidi compositus instead of antikamnia. He urges the Association to call its members back to the more conservative way of prescribing. [F.J.K.]

10.—Woldert continued his observations upon the cultivation of the **estivoautumnal malarial parasite in the mosquito** (*Anopheles quadrimaculata*) during the past winter and summer. In the neighborhood of the League Island Navy Yard, Philadelphia, on June 19, 1900, the author found both the larvae of the *Anopheles quadrimaculata* and the *Anopheles punctipennis* near a house where a case of malaria developed. From June 19, 1900, to November 11, 1900, he collected larvae of the *Anopheles* and raised 200 adult mosquitoes. He also visited many infected localities, and always found that where there is malaria there are mosquitoes. The reverse, however, does not hold, for where there are mosquitos there are not always cases of malaria. He found some larvae of *Anopheles* in the Pocono Mountains of Pennsylvania. A number of observations were conducted to see whether the *Anopheles* collected around Philadelphia were susceptible to the infection from the malarial parasite. In only one out of 10 observations did he find zygotes in the middle intestine of one mosquito. [F.J.K.]

11.—Stricker presents a diagram showing the **neuronic architecture of the visual apparatus**, the chart representing a complete cross section of the brain at a level with the optic thalami. Beginning with the eyeballs the chart portrays the optic nerve, chiasm, optic tracts, tracing the visual apparatus to the peduncles, the distribution of the fibers to the primary optic centers, and the dendrites, which in turn are in apposition with those given off by the ganglion cells in the primary centers. Furthermore, these ganglion cells give off dendrons which are sent out to the visual centers in the cortex of the occipital lobes. The association fibers, the fibers from the motor cortical areas to the motor ocular nuclei of the opposite side are shown, as are also the fibers which pass directly from the optic tracts to the centers for pupillary reaction, as well as to the third and fourth nerve. The sixth nerve and the remaining cranial motor nerves are communicated by the centripetal and centrifugal fibers contained in the posterior longitudinal bundle. The neuronic structure of the retina is described. The various theories regarding decussation are considered, as are also the third, fourth, fifth, sixth, and seventh nerves in detail. Lesions affecting the association fibers not only give rise to hemianopsia but also to other manifestations, such as optic

aphasia, alexia, soul-blindness. The nerve fibers were traced by Weigert's stain, and their origin and terminations by Golgi's stain. [M.R.D.]

1.—Vulpus believes as a result of his very successful experience that in the majority, if not in all cases of **club foot**, permanent and almost complete cure can be obtained by the method of forcible reduction of the deformity, followed by the application of a plaster cast, that is to be worn for at least 4 months. Even in adults this treatment has produced feet that are almost normal in appearance, and apparently quite satisfactory as far as function is concerned. The treatment is not entirely bloodless. He almost invariably cuts the Achilles tendon, and frequently the plantar aponeurosis, and in some cases, more extensive operations are required. In the severe cases it is sometimes necessary to use appliances to bring the bones of the foot into approximately normal relation, and it may even be desirable to overcorrect slightly. After the plaster cast has been removed, braces are often required for some time. There may be at first intense pain, which usually does not last more than 3 days, but if it should persist beyond this time, it indicates that the brace has not been properly applied, and needs attention. If, before the operation, the leg is shorter than its fellow, of course no elongation is produced, and in nearly all cases the calf muscles remain small, although the strength of the foot is usually very good. Altogether he had 37 cases, ranging from 13 to 35 years of age, and many of them have now been under observation for more than 5 years since the operation. There have been no relapses, and the results have been uniformly excellent. The only danger is the possibility of the formation of a pressure ulcer under the bandage, but even this is not to be greatly feared. [J.S.]

2.—Human milk contains from 11 to 12% of solid constituents; cow's milk, from 14 to 14.5%. Human milk contains from 6 to 7% milk sugar; cow's milk from 3 to 4.5%; although immediately after delivery human milk contains a smaller proportion of sugar. Citric acid occurs in human milk in a very much smaller proportion than it does in cow's milk. Both contain about the same quantity of fat, but in human milk there is a larger proportion of the heavy fatty acids, and a larger, finer emulsion of the fat than in cow's milk. Human milk contains very much less albumen than cow's milk, and a proportion of nitrogenous substance from 7 to 9%, whereas in cow's milk it is 1 to 2.3%. Curiously enough the quantity of albumen is greatest immediately after delivery, and then steadily diminishes, so that the total quantity taken daily by the child remains almost the same. However, the proportion of lactalbumen to casein is greater in human milk than in cow's milk. In addition there are certain nitrogenous substances, some of which contain phosphorus in combination. Cow's milk contains a larger amount of phosphorus, but most of it is in the form of inorganic salts. In conclusion Edlefsen expresses himself as rather sceptical regarding the value of certain substances, that, added to cow's milk, modify its chemistry in the direction approximating human milk, and feels that in general, ordinary cow's milk diluted, with the addition of a small amount of cream, albumen and sugar of milk, fills the required conditions. [J.S.]

3.—A man, 60 years of age, had suffered from pains in the right upper portion of the abdomen for about a year, and slight icterus, that disappeared after the employment of Carlsbad salts. He emaciated rather rapidly, and there was a distinct globular resistance in the left epigastrium, that was not painful upon pressure, and became very much less distinct when the stomach was inflated, and was evidently behind the transverse colon. The feces did not contain any abnormal quantity of fat, but there was a distinct trace of sugar in the urine. A diagnosis of tumor of the tail of the pancreas was made, and an operation performed, that revealed an **abscess** containing offensive pus, about twice the size of a fist. Cultures showed the presence exclusively of the diplo-bacillus of Friedländer. The 3 forms of pancreatic disease amenable to surgical interference are tumor, necrosis of the pancreas as a result of inflammation, and abscess. The last is by all odds the rarest. Only 8 cases have hitherto been recorded in which operation has been performed. [J.S.]

4.—Haenel has made a considerable number of observations in cases of **gastric disease**, in order to determine to what extent the statements of Head regarding **sensory disturbances** in certain definite areas of the skin in affections of this order, are borne out by observation. In 42 cases he obtained positive results, and he believes that these constitute about $\frac{1}{3}$ of all the patients examined. The changes consist essentially in hyperalgesia and hyperesthesia. There was no particular difference between the cases of gastric ulcer and dyspepsia. There are two maximal points, one anterior and one posterior, and a third just beneath the acromion over the deltoid muscle was present in 37% of all cases of lung, heart, and stomach disease. With regard to the extent, 22 cases showed hyperesthesia restricted to the usual limits, that is the fourth and sometimes the five cervical segments, and the seventh and ninth dorsal segments. Twenty cases showed much more extensive distribution. With regard to other diseases Haenel calls attention to the interesting fact that diseases of the serous membranes give rise to hyperesthetic areas, usually coextensive with the membrane and not limited to any particular spinal segments. This he is unable to explain. Therapeutically it seems reasonable to suppose that suitable stimulation of those sensory areas might act reflexly upon the organs involved. He concludes with brief descriptions of five of the most interesting cases. [J.S.]

5.—Baumgarten has observed 220 cases of **primary contracted kidneys**, 158 in men and 62 in women. The disease is proportionately more frequent in young women than in young men, 9 women being affected before 30 years of age, and only 12 men. It is probable that this disease can be inherited, that is, it may exist at birth, or there may be a distinct predisposition; the existence of gout, exposure to lead-poisoning and indulgence in alcohol are probable etiological factors, but it seems unlikely that diabetes mellitus acts in the same way. Amyloid disease, especially that following constitutional syphilis, is also a potent factor. The renal condition may be produced either by direct irritation of the kidney or secondarily to arteriosclerosis. Baumgarten admits that the commonest type is one in which both the parenchymatous and the interstitial tissues are affected, but he also believes that there are other forms in which one tissue is involved predominantly. He gives two valuable tables, in one of which the cases are classified according to age, and in another according to cause. [J.S.]

6.—Schmidt believes that the ordinary **nipple of the nursing-bottle** has certain serious defects. It requires too little force to collapse it, and therefore it does not sufficiently develop the baby's muscles, and it necessitates the frequent opening of the mouth in order to allow air to flow into the bottle, so that the child is obliged to swallow more or less air. In addition, nipples that have been used any length of time usually have their orifices so dilated that the milk flows rapidly into the stomach and may either dilate it or cause vomiting, and this flow, together with the slight amount of work required, fails to fatigue the child sufficiently, and as a result it does not sleep after nursing. He has therefore devised a nipple which consists essentially of the ordinary finger form containing slits instead of holes at the end, which have a valve-like action, and prevent the ingress of air, and on its sides an opening that can be regulated by a screw-valve to allow air to get into the bottle. The extent to which this is opened regulates the amount of this flow, and the effort required to obtain the milk. [J.S.]

7.—Gebbart has employed **nitropropiol tablets in order to detect sugar in urine**. The method of employment is to drop a tablet into 10 or 15 drops of urine, diluted with about 10 ccm. of distilled water, and to warm slightly. If sugar is present the solution turns first green and then blue. If only a small quantity is present, this can be concentrated by shaking with chloroform, as in the indican reaction. The reaction does not occur with biliary pigments, uric acid, albumin, blood, or phosphates. Neither does it occur in the urine of patients who have been taking benzoic acid, chloral, carbolic acid, guaiacol, iodine, the salicylates, senna, or turpentine. It occurs if .03 part of dextrose is dissolved in 100 parts of water. [J.S.]

8.—The plaintiff had contracted gonorrhea, followed by epididymitis, as a result of which one testicle had been removed. He subsequently married and his wife bore two children. Certain admissions by her led him to doubt his paternity, and a medical expert, to whom the case was referred, found that spermatozoa were absent from his seminal fluid. He decided, therefore, that, although he was not the father, the plaintiff must provide for the children, because he had not suspected their illegitimacy until more than a year after birth. The author criticises this judgment because the swelling and tenderness of the other epididymis indicated a recent infection and suggested a lingering possibility that paternity had been possible. [J.S.]

9. Reply to the Remarks of Prof. Fraenkel in No. 51 of this Journal. KOPP.

1.—Eversbusch reports a case of **visibility of the ciliary processes in the pupillary area** occurring in a 20-year-old girl. Dilatation of the pupil with homatropine showed that a cataract (two corneal scars showed that a previous dissection had been done) caused a diminution in the volume of the lens not only anteroposteriorly, but also caused an equatorial shrinking. There resulted a lengthening of the ciliary processes in the whole anterior division of the choroid, most marked at the lower inner quadrant, and least marked up and out. Most careful examination of the eye with the loup could not determine whether this condition was due to an unequal shrinking of the lens in its equatorial diameter, or to the fact that the ciliary processes were drawn up over the anterior surface of the shrunken lens capsule. The operation, which was conducted under complete cocaine anesthesia (fearing loss of vitreous on account of retching and vomiting from a general anesthetic), consisted of a corneal section at the lower outer quadrant of the limbus, sufficiently broad so as to permit the introduction of Esberg's dissection-scissors. The latter were introduced into a small gap which existed between the two ciliary processes. Uninterrupted recovery followed with black and regular pupil reacting well to light, etc. The illustrations comprehensively show the pre- and postoperative condition of the eye. The literature on the subject is considered, with special reference to the cases of Siegrist and Schweigger. [M.R.D.]

2.—The authors, in continuation of their work, have cultivated a number of bacteria, found in various places, that have the following characteristics: They decompose albumen; ferment the carbohydrates with production of butyric acid and lactic acid in alcohol; they are of obligate anaerobes, and the group contains an organism that is nonmotile, and causes **glanders** of cattle. They have now several specimens of tissue from animals affected with glanders, from which they have obtained this organism. [J.S.]

3.—Kuhn has performed a number of investigations upon the urine in order to determine the presence of **indican**, using the reaction of Obermeyer and Jaffe. He was impressed during this investigation by the fact that the chloroform not infrequently was colored red or violet. This he ascribes to the presence of iodine in the urine. In order to overcome this disturbance it is only necessary to add a crystal of sodium hyposulphite in order to convert the iodine into sodium iodide. Suspecting that bromine might also develop the reaction, tests were made with this, but they showed that it had no influence. [J.S.]

4.—Braatz calls attention to the fact that in surgery it is exceedingly important not only to **sterilize** the various materials used, but to keep them sterilized. He has devised an apparatus by which this can be done very quickly and very readily. This consists essentially of a metal box that is air tight, and in which a wire basket is enclosed that contains the dressings, and permits the free access of steam to all parts. In order to increase the effect, he is in the habit of heating the dressings first in a hot air oven, and then introducing into them steam at the temperature of 100° C. [J.S.]

5.—Gossner reports the case of a man who had severe **hematuria**, associated with severe pain in the right renal region. All treatment proving unavailing, it was decided to give him a **subcutaneous injection of gelatin**, and 200 ccm. of a sterilized 2.5% solution was introduced into the right breast. The injection was intensely painful, and associated with considerable swelling, but the hemorrhage stopped within 24 hours, and there was no recurrence. [J.S.]

6.—Morian reports the case of a man, 42 years of age, who was rushed by a heavy bucket in a mine. He was rendered unconscious for some time, and the same day, when inspected in the hospital, it was noted that his face was deep blue in color and swollen; there were hemorrhages from the nose and mouth; minute ecchymoses in the skin, covering the upper portion of the body, and involving also the mucous membranes, with the exception of the neck, where there was a white mark corresponding to the pressure of a collar. The left leg was completely paralyzed, the right almost completely; the knee-jerk was lost, and it was necessary to use the catheter for 11 days. At the end of 10 weeks the patient had improved considerably and commenced to walk. The author has collected 8 similar cases from the literature, 2 of which died in a very short time, the other 6 completely recovered. He believes that the condition was produced by pressure upon the viscera partially equalized by closure of the glottis. He prefers the name "**pressure congestion**" suggested by Berthes to "congestive hemorrhage after compression of the body" suggested by Braun. [J.S.]

7.—Cramer believes that in those cases in which the head refuses to engage in the pelvis, it is desirable to use pressure through the abdominal walls in order to compel it to do so. For this purpose he prefers pressure with the closed fist by which it is possible to exert a force equivalent to 70 kilograms or more. He has used this procedure in 6 cases with excellent results, and with no complications. [J.S.]

Berliner klinische Wochenschrift.

January 21, 1901. [38. Jahrg., No. 3]

1. Diseases of the Hip Joint. KÖNIG.
2. Mania with Depression. WEYGANDT.
3. Two Cases of Rupture of the Ductus Arteriosus Botalli. ROEDER.
4. Gallstones. RIEDEL.

1.—König describes **gonorrheal coxitis and arthritis deformans** of the hip-joint. He believes that the former variety is a peculiar disease, and occurs more frequently than has been supposed, in consequence of which there are many errors in diagnosis and treatment. Observation of his twenty cases shows that **gonorrheal coxitis** occurred usually between the ages of twenty and forty years, eleven times in females and nine times in males. The disease occurred principally during the acute stage of the gonorrhea, although it also occurred during the chronic stage. Trauma preceded the affection in five cases. Pregnancy appears to favor the onset of gonorrheal coxitis. This also applies to

the puerperium, an observation which is of value, as it may explain many cases which have been diagnosticated as due to puerperal sepsis. Frequently the affection is bilateral; varies in intensity; frequently there is simultaneous involvement of other joints. The author has frequently observed during the latter stages of gonorrhea that the process also affected the vertebral joints, with a tendency to ankylosis. Clinically there are two varieties: those where the onset of the pain is gradual, as is also the restriction of motion in the affected part, and those in which the onset is characterized by marked disturbances of motion, the most severe pain, and a plainly demonstrable tumor. In the stage of the process in which the patient generally presents himself at the hospital, pain is the predominant symptom. In a relatively small percentage of cases anomalies in the position of the extremity and contracture do not occur. Much more frequently, however, moderate flexion with abduction and external rotation are present. The extremity with the patient in the horizontal recumbent position appears lengthened. This was observed in one half of the author's cases. In one quarter of the author's cases there existed a condition which according to him endangered the later functional activity of the joint, namely, flexion, with adduction and internal rotation, and which with the patient in the recumbent position showed apparent shortening and luxation. The author has noted actual shortening in these cases of from 2 to 5 cm. A very constant symptom of gonorrheal coxitis is the swelling of the joint, most marked at the anterior portion, often fluctuating, and occasionally assuming a phlegmonous character. During the acute stage this swelling is sometimes accompanied by a moderate fever. Without treatment the majority of cases terminate in a pitiful manner. Almost one-third of the author's patients recovered with more or less shortening. Impairment of mobility regularly follows, sometimes hampering the ability to stand or sit. Occasionally the author was only able to correct the deformity by force. The prognosis as far as function is concerned is not good. Five of the author's cases recovered without disturbance of mobility. Of the remaining cases one-half recovered with slight impairment of mobility, while in the balance marked disturbances of mobility, shortening, ankylosis and abnormal positions resulted. König is of the opinion that the latter cases would have terminated more favorably if treatment had been instituted very soon after the onset of the disease. Although the author has had no experience in the application of plaster-of-Paris bandages to the hip joint, he is of the opinion that an accurately applied plaster-of-Paris bandage would lessen the pain and hasten the recovery, as it does in the elbow, hand and knee. During the acute stage of the process surgical intervention is but rarely required. When ankylosis occurs, indication for surgical interference depends upon the position of the part. According to the position, either osteotomy or resection may have to be done. König believes that **arthritis deformans** affecting the hip joint is a typical affection, although we are not yet in the position to demonstrate its etiology as we can in tuberculosis or gonorrheal arthritis. The pathological anatomy shows a marked panarthritis involving the joint and capsule. Arthritis deformans of the hip occurs as a monarticular process, although beginning changes in other joints are also frequently found. The author describes 20 cases coming under his observation. Among these, 16 were over forty years of age, 12 were over fifty, and half of the latter were sixty and over. Among the younger patients observed by the author, inflammatory processes (acute osteomyelitis) or trauma had preceded the arthritis which, however, did not occur as a rule in the typical cases. Among König's 20 cases, 17 were males and 3 females. Hard-working persons like farmers and laborers seemed to be more frequently affected by this disease than others. The beginning of the disease is usually ushered in by subjective difficulties. Patients complain of a grating sensation in the region of the hip, which is most annoying in the morning upon rising. Disturbances of motion soon follow which, as a rule, first become manifest in the attempt of abduction. The pedestrian complains that he experiences great difficulty in stepping over ditches which he previously could cross with ease, and the rider finds great difficulty in swinging his leg over the saddle when mounting. Abduction and adduction soon increase in difficulty, and rotation becomes

almost impossible. Finally the members can be bent only in one horizontal axis, and, as a rule, the foot assumes a position midway in rotation. Some patients experience great pain which becomes either periodical or becomes manifest at every moment. In time there occurs more or less ankylosis of the hip. The disease is not typical as far as its development and progress is concerned. The author has never seen complete recovery in a case of arthritis deformans of the hip-joint. The treatment of arthritis deformans depends upon the individuality of the case. König believes that the most efficient manner of treatment is to begin with regular movements of brief duration, whose purpose is to prevent a deformity in one axis. This treatment must be continued for some time. Should symptoms of irritation with increased pain occur, the exercises are to be stopped and a period of rest advised. The symptoms of irritation are relieved by extension treatment. In some cases resection is the only remedy left. The author reports several cases operated upon, the technic of his operation, and the history of the patients. [M.R.D.]

2.—Weygandt believes that 90% of cases of **mania with depression** are hereditary. The patients generally manifest symptoms of disease during youth by certain peculiarities of character and spirits. The first attacks generally occur during puberty, the disease then showing marked periodicity. The maniacal condition is characterized by excitement and flighty ideas. The other phase, by dejection, and interference with the association of thought. [M.R.D.]

3.—Roeder reports two cases of **rupture of the ductus arteriosus Botalli**. One child was born in breech presentation and in the other there was an enlargement of the thyroid gland up to three times its normal size. The author believes that the cause in most of the cases is a marked disturbance of the circulation occurring in his two cases during birth. From a histological and hemodynamic point of view it appears that the opening of the ductus into the aorta can normally only occur at acute angles. [M.R.D.]

4.—Riedel reviews the literature on **gallstones** since Sæmmering published, in 1795, his work entitled "*De Concrementis Biliariis Corporis Humani*." The formation of gallstones is a harmless process as long as the cystic duct remains open; the bile produced in the liver may go through the gallbladder and flow over gallstones without producing any troublesome symptoms. The author believes that hydrops is not caused by the closure of the cystic duct, but by impaction from a stone in the neck of the gallbladder. The clinical course of the affection is not dependent upon the nature of the fluid in the gallbladder; seropurulent fluid may give rise to severe attacks and pure pus may not cause any symptoms for weeks or months. Among 151 cases of "gallstones" the fluid contents in 76 cases consisted of serum, mucus in 16 cases, and pus in 36 cases. In 23 cases in which bile was present, the latter was inspissated in 14 cases, turbid in 7 cases, and clear in 2 cases. Most of these 151 cases had a large and the longest existing stone impacted in the neck of the bladder; this was sometimes the only one, but most frequently there were several generations of stones of similar size that had developed in the direction of the fundus. As long as the occluding stone remains in position inflammatory exudates may be absorbed, and the distended gallbladder again becomes softer and smaller. We now know that primarily, in violent biliary colic, there is almost always serum in the gallbladder, and it requires a rapidly accumulating serous exudate, with a wall of the gallbladder relatively intact, to permit of the further progress of the gallstone. The author agrees with Sæmmering that **icterus** occurs in about 10% to 15% of cases where the stone remains quiet in the neck of the gallbladder. Riedel has termed this variety of icterus as **inflammatory** in contradistinction to that variety caused by the lithogenous process, when there is an impaction of a stone in the ductus choledochus and which causes an inflammation of the gallbladder extending to the entire biliary system. Although it has recently been attempted to explain this variety of jaundice as due to the distended gallbladder pressing upon the ductus choledochus, this explanation according to the author is not tenable because this icterus is also seen in small shrunken gallbladders, and even after operations when the drainage tube has been removed too early. The character of the affection changes suddenly when a more or less harmless local process develops into a general affection. The ordinary everyday onset of the affec

tion of the process is a rapid distention of the anterior abdominal wall, vomiting and pain radiating to the right shoulder; the absence of icterus may then give rise to a suspicion of gastralgia following a gastric ulcer, when no gallbladder is palpable, and a floating kidney or appendicitis may be diagnosed when a tumor is present below the liver. Errors are also made when there is a palpable gallbladder. If the latter decreases in size with an abeyance of the symptoms, many physicians still suppose that the diminution in the size of the tumor is due to the passing of a stone through the cystic duct. Furthermore, when the patients do not have icterus and no stones are found in the dejecta, this statement is made; "not every patient has icterus;" or, "the stones in the feces have been overlooked." As a matter of fact in these cases the stones have not been moved in the slightest degree, but the inflammatory tumor has undergone spontaneous retrogression, similar to that process seen in gouty joints. Most of the patients have a watery fluid in the gallbladder, not bile, and have a large calculus, not a small one impacted in the neck of the gallbladder. The older view on this subject is only applicable in the minority of cases, namely in those where there is inspissated bile in the gallbladder and where there is a small stone; in these cases an effusion of serum may push the stone out. Regarding the indications for the treatment of these affections the author is of the opinion that among the cases **not** to be operated upon are those where the first paroxysm of pain is succeeded by all the typical manifestations, where the patient becomes jaundiced on the second to the third day and passes small stones *per vias naturales*. Even repeated attacks are not indications for operations when each time small stones are passed. When there are numerous attacks without the passage of small stones then the question of operation arises on account of the suspicion that besides the small calculi there may also be large ones impacted in the gallbladder. Furthermore those cases should not be operated upon in which after repeated ineffectual attacks larger calculi have been passed; for if a large stone has been passed others may follow. If ineffectual attacks continue to follow, operation is indicated. On the other hand, a single ineffectual attack without jaundice indicates operation; the calculi should not be pushed deeper by further attacks, but should then be abstracted. We have no one single remedy to bring about a state of latency. The latter may be partially at times brought about by aperients, but even then it is of short duration. Operation is indicated in those cases when after repeated ineffectual attacks the uppermost stone enters and becomes impacted in the ductus choledochus. Of course this impaction must be determined by waiting for some time; from 2 to 3 weeks is sufficient, although a patient rarely permits himself to be operated upon so early, because he still hopes of a spontaneous evacuation of the calculus. The earliest choledochotomy performed by the author was 6 weeks after the entrance of 3 stones into the ductus choledochus; one of these was spontaneously evacuated in a natural manner, and the two others were abstracted from a ductus choledochus that had become as thick as a finger; uninterrupted recovery followed. The physician must not only make a general diagnosis of gallstones, but in every case must establish the position of the calculus, its presumable size, and the nature of the contents of the gallbladder. In this way it will be elicited what cases to leave to nature, and upon which to operate. Some of the literature on the surgery of gallstones is reviewed. [M.R.D.]

Wiener klinische Wochenschrift.

January 31, 1901. [14. Jahrg., No. 5]

1. The Umbilical Cord in Newborn Infants. MAX STOLZ.
2. Four Cases of Plastic Induration of the Cavernous Bodies of the Penis. OTTO SACHS.
3. Further Communications upon Operation for Volvulus. JOSEPH PREINDLSBERGER.

1.—Stolz reports his results, in 500 cases, of his treatment upon the **umbilical cords of newborn infants**. One hour after the umbilical cord has been ligated at some distance from the navel, he **ligates the cord remaining, close to the navel with a fine silk thread, and snips off the cord a half centimeter above that with a**

sterile scissors. Sterile gauze is then applied, and a bandage put over it for safety. This is dressed every second day, when the child is weighed, the dressing being continued even a few days after the cord sloughs off. The stump appeared dry, with very slight secretion at any time. In most cases the cord dropped off upon the fifth, sixth, or seventh day (309 out of 500). The average time was 6½ days. It was not true that the cord healed any quicker in the stronger or heavier children. There was no relation between body weight and the time the cord dropped off. Nor did the character of the food make any difference. But it was striking that in the children of parents suffering from slight puerperal diseases, the cord dropped off later, after 7 days. This was possibly due to slight infection of the stump, with secretion following. The after care may have caused it, however. Only one case of hemorrhage occurred, and that was from the slipping of a ligature, as the cord had been cut too close to it. Finally, he advises great care in treating the stump, to keep the wound aseptic and dry. [M.O.]

2.—After a thorough review of the reported cases of **induration of the cavernous bodies of the penis**, their causes, course, and treatment, Sachs gives the histories of his 4 cases, the causes for which are unknown. In all, when past middle age, circumscribed hard masses appeared on the dorsal surface of the penis, near the median line, preventing complete erection. Nothing showed in skiagraphs, so that they were probably due simply to connective tissue. They came on very slowly, during two years or more, and caused pain only upon erection. The diagnosis of the affection is easy. No local treatment has had any effect thus far. Internally arsenic and potassium iodid have been given. Patients should be assured that the affection is not serious, as it may lead to melancholia. [M.O.]

3.—Preindlsberger reports two cases of **intestinal obstruction**. The first was a farmer, aged 25 years, who had had gastroenterostomy performed for stenosis of the pylorus. Two years later he was again operated on, this time for intestinal obstruction. The small intestine was found twisted upon itself beneath the site of the former operation, probably due to the shrinking of the cicatricial tissue of the mesentery, the intestines, or both. The other case occurred in a man 51 years old, who died after operation. **Meckel's diverticulum** existed, was very long, and had become **adherent to the abdominal wall**. Under this the small intestine was twisted upon itself and incarcerated. Though laparotomy was performed with local anesthesia, he died 24 hours later. Both cases occurred in Herzegovina. [M.O.]

February 7, 1901. [14. Jahrg., No. 6.]

1. Disease of the Nasal Mucous Membrane a Common Occurrence Among Turners. RUDOLPH BLUM.
2. Hysteric Facial Diplegia. HUGO LUKACS.
3. Foreign Bodies in the Male Bladder. FRITZ PENDL.
4. A Method of Preventing Clouding of the Mirror in Nasopharyngeal Examinations. ERNST URBANTSCHITSCH.

1.—In spite of the dust extractors, and other modern inventions employed in cane factories, large quantities of **dust come in contact with the nasal mucous membrane of the turners** at work. Besides, the hazelwood used has first been soaked in potassium dichromate, which substance itself causes inflammation of the nasal mucous membrane. Small blisters first appear, then ulcers follow, after which hemorrhage occurs. Later membranes may form, or rarely ozena results. As a rule nothing is noted externally; but internally an **advanced atrophic condition** is finally developed. Besides the care taken by the proprietors of the factories to prevent the accumulation of dust, all new workmen should be made to wear a sponge, moistened with vinegar, over the mouth and nose, to counteract the potassium dichromate. When this atrophic condition exists, daily local treatment will do good, if continued regularly. [M.O.]

2.—Lukacs reports a rare case of **hysteric facial diplegia** in a girl of 19. Right facial paralysis occurred 3 years ago, with pain on pressure over the point of exit of the right facial nerve. Electricity cured this in 3½ months. Six months later the right facial paralysis again appeared. This was also treated electrically. A week later the left side became paralyzed. Her facial expression changed almost like the "mask" of Parkinson's disease. She was easily

hypnotized, but presented no stigmata of hysteria. During 14 months' treatment, this condition has varied but little, at one time better, then worse again. Tonic contractions of the muscles of the mouth have appeared, lasting several minutes at a time. Voluntary movements are carried out, though limited in extent. They are done better when she is hypnotized. No reactions of degeneration have appeared at all. A review of the literature of the subject follows. [M.O.]

3.—Pendl reports 2 cases of **foreign bodies in the male bladder**. In the first case, a boy of 2 years, he extracted a **needle, its eye end embedded in a calculus**, by suprapubic cystotomy. He believes that the presence of the needle in the bladder is most probably due to the child having swallowed it, the needle then having perforated the intestine, and reached the bladder. In the second case, a man, of 38, he performed lithotomy, crushing about **20 pieces of paraffin**. Though the history is obscure, it is supposed that the patient had introduced paraffin sticks into the urethra. He gives the literature of the subject in full. [M.O.]

4.—Urbantschitsch has experimented with **lasin**, a substance which, when spread upon the mirror to be used in nasopharyngeal examinations, prevents the breath from clouding the mirror, and does away with the necessity of heating the mirror before introducing it. It is spread upon the mirror, and lightly wiped off, so that the mirror remains bright, yet all the moisture is at once absorbed by the lasin. To disinfect the mirror, a 10% solution of carbolic acid is used, and then the mirror is washed in water before the lasin is again spread upon it. [M.O.]

Centralblatt für Gynäkologie.

1. F. Ahlfeld and the Tübingen Method of Hand Disinfection. TH. PAUL and O. SAWAY.
2. Remarks on the Open Letter of the Geheim. Medicinrath Professor Dr. Ahlfeld to Herr Privatdocent Dr. Kriönig. KRIÖNIG.
3. Kolpeurysis and Metreurysis. ARTHUR MUELLER.

1.—The authors object to the criticism of Professor Ahlfeld on the **method of hand disinfection** as employed at the University of Tübingen. Ahlfeld prefers the hot-water method to that of the soap and alcohol of the latter institution. They claim that Kriönig had not spoken in opposition to their method, as Ahlfeld had stated, and that Professor Ahlfeld is in fact the only authority up to date who has found fault with their method of disinfection of the hands. They assert, on the other hand, that Professor Kriönig was astonished at the results obtained by their method, and openly acknowledged the value of the Tübingen process. They emphatically state that Ahlfeld's criticism is absolutely unfounded. It is difficult to say, they admit, which method of disinfection gives the best results, namely: the method as employed by them or that of Hagler and Kriönig. [W.A.N.D.]

2.—Reinicke stated that after 10 minutes of **immersion of the hand in alcohol**, no living spores could be found on the epithelium. Kriönig remarks that this is a mistake, and that the bacilli will be found without a doubt after this method has been employed. He has demonstrated that after 15 minutes immersion of the hand in alcohol, anthrax germs were still present, as was shown by inoculating mice, the animals quickly dying of the infectious disease. He believes that many pathogenic forms of bacilli exist which have as yet not been recognized, and that many of these germs will not be destroyed by this method of disinfection. [W.A.N.D.]

3.—Mueller endorses the method of dilatation of the vagina and uterus by means of elastic balloons or bags for the **induction of premature labor** in preference to the performance of the more serious operations of cesarean section and symphysiotomy at term in cases of pelvic contraction. The bags may be retained *in situ* for from 8 to 5 hours, or, if necessary, even up to 31 hours. The bags that he prefers are modelled somewhat after those of Champetier de Ribes. [W.A.N.D.]

1. Autocystoplasty and Kolpocystoplasty in Marked Defects of the Vesico-vaginal Wall. O. WITZEL.
2. On the Favoring Influence of Pregnancy upon Enteroptosis. HECTOR MAILLART.
3. Cure of a Bilateral Salpingitis—Probably Tuberculous—Through an Atrophy Secondary to Ligation of the Vessels. MAX NASSAUER.

1.—Witzel emphatically condemns the operation of kolpokleisis for the cure of **gross defects of the vesico-vaginal wall**, on the ground of the ultimate development of serious complications, which result from infections originating in the retained vaginal secretions. He remarks that the bladder very shortly becomes the seat of a chronic cystitis which, sooner or later, extends up the ureters to the kidneys. The end is a septic pyelonephritis. He describes the case of a woman, 46 years of age, who presented a marked vesico-vaginal fistula in which 3 unsuccessful attempts had been made to close the opening, which had resulted from attempts at the removal of a myomatous uterus. His examination of the patient convinced him that there was a possibility of intravesical transplantation of the ureters, and he resorted to an extensive kolpocystoplastic operation to remedy the defect. Full exposure of the seat of operation was obtained by digital retraction of the anterior vaginal wall and the use posteriorly of a large-sized speculum. It was found that the destruction of tissue had partially involved the posterior wall. By means of the finger the bladder was loosened from its surrounding tissues after a transverse incision had been made into the vaginal wall, and the organ thus rendered more accessible for the further necessary manipulations. Slight traction was then successfully exerted upon the posterior wall, which was drawn forward to cover the deficiency in the anterior tissues, a few stitches then sufficing to bring the parts into active apposition, Lembert's sutures being employed for this purpose. A large-size Néaton catheter was introduced into the urethra and retained in position for a few days. The wound made an uninterrupted recovery. There was but little discharge from the vagina following the operation. [W.A.N.D.]

2.—Maillart has for several years been paying considerable attention to the association existing between **pregnancy and enteroptosis**. After giving a thorough review of the literature of the subject, he describes several cases of the condition which had occurred in his own practice, and finds that there exists a certain relationship between the enteroptosis and a condition of congenital neurasthenia. He concludes that since in cases of ptotic individuals becoming pregnant, the intraabdominal pressure increases rapidly as soon as the uterus has attained a certain volume, and since pregnancy under these circumstances produces a marked improvement in the digestive functions and in the general neurasthenic condition—an improvement which gives rise to an increase in weight of from 2½ to 6 kilograms from the time of conception until the end of the puerperium—it follows that by proper treatment this improvement, which seems almost to amount to an absolute cure, may be made lasting. This permanent improvement especially manifests itself in the latter months of pregnancy, and induces a further increase in weight of several kilograms. In those cases in which from some other cause, such as albuminuria or neglect of a proper handling of the case, this improvement of the general condition is arrested, even then a normal pregnancy exerts no evil influence upon the ptotic condition, not even in the cases in which there is associated a constituted neurasthenia. [W.A.N.D.]

3.—Nassauer takes exception to the statement of Lindfors published in No. 41 of the *Centralblatt für Gynäkologie* that a case of **bilateral salpingitis, probably tuberculous in nature**, had been cured by an atrophic process resulting from ligation of the vessels on that side of the broad ligament. He prefers to believe that the beneficial result was not the direct outcome of the arterial ligation, but that it resulted from the alternative effects following the abdominal incision which, as is recognized, gives rise to a marked improvement in the circulation of the pelvic tissues in tuberculous cases whereby there follows an amelioration and in many cases an absolute cure of the tuberculous process. This, he believes, results from the improved nutrition consequent upon the increased circulation of the blood. [W.A.N.D.]

FALSE PREGNANCY (PSEUDOCYESIS) AND
MYXEDEMA.By EDWARD P. DAVIS, A.M., M.D.,
of Philadelphia.Professor of Obstetrics in the Jefferson Medical College; Professor of Ob-
stetrics and Diseases of Infancy in the Philadelphia Polyclinic;
Visiting Obstetrician to the Jefferson, Philadelphia,
and Polyclinic Hospitals, etc.

GENUINE pregnancy, whether entopic or ectopic, is often difficult to recognize. Still more puzzling are cases of false pregnancy. The circumstances under which they arise are calculated to mislead the practitioner. The patient's positive assertion, her accurate description of symptoms, the abdominal tumor, indefinite mammary changes, and the preparations made for the expected confinement render an error easy. The task of undeceiving a woman strongly desirous of offspring is a thankless one. But the resentment which such a patient feels when allowed to go to a supposed labor must be most annoying to the physician and detrimental to his reputation.

Accusation alleging criminal assault by innocent persons are not infrequently made by patients who assert that they are pregnant. Here the physician's diagnosis destroys one of the strongest evidences in favor of the really guilty party. The following cases illustrate this condition:

CASE 1.—A robust woman, of gouty tendency, married later than the average age of marriage. Of an affectionate disposition, the birth of a child would have been most acceptable. After marriage menstruation became disordered, being greatly diminished in quantity and attended with far less pain. The breasts increased considerably in size, the patient became stouter and increased markedly in the development of the waist. The abdomen increased in size and the patient alleged that she felt movements of the fetus. Her married sister, the mother of several children, had a periodical discharge resembling menstruation throughout each pregnancy. This led the patient to believe that menstruation in her case was no proof that pregnancy was absent. When the patient was first examined, the womb was slightly enlarged, the cervix softened. She was informed that pregnancy might be present, but that positive evidence of it was lacking. Examinations at intervals sufficiently long to recognize growth in the uterus proved that such growth was not taking place. The patient was thoroughly convinced that she was pregnant and that if she was not pregnant she had an abdominal tumor of considerable size. At the suggestion of her physician she was examined under ether and in consultation with a second physician. The pelvic organs were found normal in size, position, and consistency. The patient accepted the result of the examination and willingly submitted to treatment by massage, regulated feeding and exercise. Her increased weight diminished to normal, the abdominal tumor disappeared, and she speedily became convalescent.

In this case marriage was followed by increase in general physical development, a result not infrequently seen. The patient very naturally reasoned from the experience of her sister, and from incidents which she had heard from other women, that she was in the pregnant condition and continued so to think. Her recovery to sound health was greatly hastened by her good sense in accepting the result of the examination and in cooperating with the treatment proposed.

CASE 2.—A girl, aged 16, had been an inmate of several charitable institutions, giving the following history. She had been criminally assaulted and had become pregnant. The

exact period of gestation she could not describe nor remember, but her statement as to the occurrence was positive and she was prepared to make a charge against an individual. She described minutely the symptoms usual to pregnancy.

On examination the abdomen was enlarged to eight months' gestation. The breasts were also enlarged, the nipples more prominent than usual, secretion was not present. Upon palpation, the position of the fetus could not be definitely outlined nor could much be learned regarding the nature of the abdominal tumor. Fetal heart sounds were not heard. As it was necessary to ascertain definitely the patient's condition, she was anesthetized. As the anesthesia proceeded the abdominal tumor gradually disappeared, and it was possible to grasp the uterus between the hands in making the examination, and to demonstrate in clinic the fact that pregnancy was absent. Prolonged observation of this patient proved the truth of the diagnosis. She could at will produce the abdominal tumor and did so whenever she wished to attract attention.

This patient may have been immoral, and was certainly malicious in so far as her declaration that pregnancy existed was concerned. She evidently used this declaration to attract attention, to secure lodging in charitable institutions, and with the hope of ultimately getting money.

That pseudocyesis is a neurotic state has long been recognized. Its association with other well-marked neurotic symptoms receives abundant illustration in the following:

The patient was a stout woman of pallid complexion, aged 33. She gave a family history of heart disease. When thirteen she was thrown from a horse. Her menstruation had never been attended with great suffering. She gave a history of enteric fever and also of so-called brain fever. She had been married twice. In the first marriage, she had two miscarriages at about seven months. Her last marriage was three years ago. Since then she had menstruated regularly. For almost a year she had had milk in the breasts, and for a number of months she had felt fetal movements. Some time before she experienced well-marked nausea. Some eight months previously she had labor-pains and was supposed to be in labor. She passed nothing but clots. Since that time she has felt fetal movements, the abdomen has been most of the time enlarged, and milk has been present in the breasts. She has had headaches for years, has a fair appetite, her bowels move regularly and she sleeps badly. She would be glad to have a child, and when supposed to be in labor recently, she had a nurse in attendance and a physician remained in the house during the night, expecting the birth of the child. She asserts that she had strong labor-pains and that the doctor could not tell what had become of the child.

The results of the examination of this patient were as follows:

The cranium was narrow and the vertex high and pointed. The patient was evidently anemic and the thyroid was found enlarged. Upon questioning the patient, she stated that she had taken tablets for that condition. The left half of the gland was larger than the right. The intercostal nerves were tender and the patient's tissues were flabby. She was fat and much above her normal weight. In the left breast there was a small portion of hard glandular tissue from which milky fluid exuded. No fluid came from the right breast. Both breasts were flabby and there was no increase in the pigment about the nipples. The thoracic organs were normal. The abdomen was fat, its walls flabby, with marked tympany over the large bowel and modified tympany over the entire abdomen. The urine was normal and the blood-count showed a slight anemia.

The patient was seen by Dr. Dercum, who examined the nervous system, and by Dr. Hansell, who examined her eyes.

Dr. Dercum found her a neurotic patient, partially recovered from myxedema. Dr. Hansell found slight

hypermetropia in both eyes, and observed that the patient was wearing glasses which did not fit her.

This patient was examined under ether, when the genital canal was found relaxed, the womb subinvolved but no evidences of pregnancy present. Her perception of fetal movements ceased upon learning the result of the examination.

In the case just described, the history of abortion and the subinvolution found showed that a center of irritation was present in the genital organs. This was probably the exciting cause for the imaginary pregnancy. The predisposing cause which rendered this condition possible lay in the patient's malassimilation and neurotic state. The recognition of this condition with the local findings made the case readily intelligible.

In diagnosing false pregnancy, the physician must not be misled by ectopic gestation. It is possible for a patient to have an ectopic embryo, to manifest many of the signs of pregnancy and yet upon vaginal examination to be pronounced in the non-pregnant state. In such a case, examination under ether is of especial value, as it enables the physician to map out the pelvic contents as accurately as possible.

In patients with thick abdominal walls or with those who relax badly under ether, exact diagnosis may be most difficult. Close observation, however, will usually show that the patient has not an ectopic pregnancy, while if such be present, rupture and the symptoms which follow it must soon make clear the diagnosis.

Examinations to determine the existence of pregnancy, and especially in cases of false pregnancy, should invariably be made in the presence of a third person and whenever possible with the cooperation of a trusted assistant. In cases where an abdominal tumor has been present and where the family of the patient may believe her pregnant, it is well to demonstrate to her husband or relative the fact that the abdominal tumor disappears under ether, and that bimanual examination proves the womb to be empty.

The physician can act the part of a friend to many of these patients by protecting them, if possible, from gossip. If the supposed condition of pregnancy has become known, the patient may be greatly mortified to have the true condition announced. The physician should not only absolutely avoid statements of any sort regarding the case, but he should take pains to discourage gossip whenever possible.

It is a mistake to allow patients having false pregnancy to go with an examination only and without treatment. The source of nervous irritation giving rise to the supposed pregnancy should be removed, the nutrition of the patient stimulated as vigorously as possible and her general condition brought as nearly to the normal as the circumstances permit. The examination may reveal some pelvic disease, which must be dealt with by operative or other treatment. Where the patient can afford it, rest in bed, massage, careful feeding, electrical treatment and a selected diet are indicated.

Institute for Backward Children.—An Institute for the instruction of children of defective intelligence has been opened in Rome.

German Congress of Otology.—The German Otological Society will hold its annual meeting this year at Breslau, May 24 and 25. The arrangements are in charge of Professor Kuemmel, Thiergartenstrasse 53, Berlin.

THE ACTIONS OF MORPHIN UPON METABOLISM, WITH ESPECIAL REFERENCE TO "INTERNAL SECRETION" AND ITS BEARING UPON TOXICOLOGY.

By EDWARD T. REICHERT, M.D.,

of Philadelphia.

Professor of Physiology in the University of Pennsylvania.

[From the Physiological Laboratory of the University of Pennsylvania.]

FOR nearly fourscore years morphin has held a most important place in the armamentarium of the clinician, yet our knowledge of its physiological properties is fragmentary and unsatisfactory. It is universally recognized that this poison kills almost invariably by paralyzing the respiratory center, but to what extent this paralysis is due to direct and indirect actions is merely speculative. If it be conceded that morphin acts directly upon the metabolic processes of the center which are specifically concerned in the discharge of respiratory impulses, it must also be admitted that this action is reinforced by the enfeeblement of the circulation, by the lowered temperature, and probably by a universal depression of metabolism that not only directly but indirectly affects both its anabolic and katabolic processes. That morphin is a depressant of nearly all forms of metabolic activity, both special and general, is evident from many facts: Its power to annul the pangs of hunger and lessen the quantity of food required for subsistence; its lessening of the body-weight; its weakening of the reproductive powers of habitués; its enfeeblement of the higher mental processes; and its depression of secretory, circulatory, respiratory and muscular activity, and of body-temperature, etc., all point to a decrease of metabolism so widespread as to extend to the important processes which are concerned in internal secretion and in repair. If morphin be thus so extensive a depressant, it follows that in dealing with poisons of this class we must consider not merely the direct actions upon the vital centers, but the indirect actions which result from the metabolic depression of remote and apparently unrelated structures, by which the centers may no longer be properly supplied with some special forms of pabulum, or with other substances essential to their normal activities.

While our knowledge of the actions of internal secretions* is extremely limited, it is sufficient to warrant the belief, that they play important parts in many or in all of the vital processes; that they may affect either anabolism or katabolism; that the removal of the thyroids, adrenals or pancreas is inimical to life because of the loss of their functions of internal secretion, and the consequent effects upon general nutrition; that the respiratory disturbances in uremia are not due to the retention of urinary constituents in the blood, but to the interference with internal secretion by the kidneys; that after the removal of three-fourths of the total kidney-weight, animals may live for weeks, and die of asthenia without their being either coma or convulsions; that the marked respiratory excitement caused by muscular activity is due to substances given to the blood by the muscles; that some of the principles are more or less powerful excitants to the respiratory center, to the heart, to the cardiac centers, or to the vasomotor centers or peripheries; that some are apparently dynamogenics, increasing volitional muscular power and

* The term "internal secretions" is here used to include all substances which are specifically or incidentally produced by the various structures of the body, and destined to affect the metabolic processes of other structures than those in which they are formed.

lessening fatigue; that several are of great toxicity, one obtained from the adrenals being among the most powerful poisons known, 0.00009 gram causing marked effects upon the circulation in a dog.

The manifest importance of this subject led me to make a number of experiments on dogs with the view of studying the actions of morphin not only upon general metabolism, but their bearing upon toxicology. The calorimetric method was chosen because of its being generally preferable to the others. This method is based on the fact that the heat produced in any structure is proportionate to the degree of metabolic activity of that structure; therefore, the heat produced by the entire organism during any given period is an index of the mean degree of activity of metabolism in all of the tissues. Inasmuch, however, as each structure is to a large extent independent in its chemical processes of those in others, this index can be applied as a standard to each organ only in conjunction with what special evidence exists regarding the metabolism in that organ.

The average minimal lethal dose of morphin for dogs, when injected subcutaneously, is from 0.25 to 0.45 gram per kilo of body-weight, the mean minimal lethal dose being about 0.35 gram per kilo. Notwithstanding the comparatively large quantity required to kill, fractional doses are sufficient to cause decided effects. One thirty-fifth of the average minimal lethal dose, or 0.01 gram per kilo, is promptly followed by stupor, depression of the circulation; marked weakness, especially in the hind legs, the animal often being unable to stand, and if so, the hind legs are almost if not completely paralyzed; a fall of body-temperature, usually as much as 1.5° to 3.5° C. (2.7° to 6.3° F.); lessening of sensitivity; and many other manifestations of nervous, muscular and secretory depression, although in many instances the respiratory movements are for a time increased in depth or frequency, or in both. An increase of the respiratory rate to 200–250 per minute is not rare. A dose of 0.15 gram per kilo is sufficient to cause paralysis of the hind legs, which may last for two days. The psychic depression, the slow full pulse, the lowered arterial pressure, the slow quiet respirations, the intense muscular weakness and the decided fall of body temperature are among the most marked phenomena commonly observed in morphin poisoning.

Twelve experiments were performed. In each the heat processes were studied for 1 or 2 hours before giving the morphin,* and from 3 to 5 hours after. The results, as shown in the accompanying condensed records, were decided and quite uniform. In the first 10 the dose was 0.01 gram per kilo of body-weight; in Experiment 11, 0.07 gram per kilo; and in Experiment 12, 0.15 gram per kilo. In every experiment a fall of temperature occurred, the maxima being 3.66° , 2.10° , 0.91° , 1.57° , 0.93° , 2.30° , 3.76° , 1.69° , 1.24° , 0.93° , 1.35° , and 2.77° , respectively, and the average 1.93° . As a rule, the temperature begins declining during the first hour after morphin, falls rapidly during the second hour, and but little more during the third hour, and sometimes continues downward during the fourth hour. In every case the temperature fell during the second hour. In 4 experiments (Nos. 8, 9, 11, and 12) there was an increase during the first hour, notwithstanding the occurrence of a decrease of both heat production and heat dissipation, the former, however, not being lessened so much as the latter. In 5 (Nos. 1, 5, 6, 7, and 10) the temperature fell continually throughout

the 4 hours. In 2 (Nos. 3 and 8) rises of 0.21° , and 0.8° , respectively, occurred during the third hour. In 4 (Nos. 2, 4, 8, and 9) rises of 0.16° , 0.11° , 0.87° , and 0.33° , respectively, were recorded during the fourth hour. The minimum temperature was in 2 experiments noted during the second hour; in 5, during the third hour; in 4, during the fourth hour; and in 1, during the fifth hour. The extent of the decrease is due, in part, to idiosyncrasy, as will be apparent by comparing the figures of the 10 experiments in which the dose was the same, and also by a comparison of these with the results in Experiments 11 and 12, in which the doses were very much larger.

Heat production was decreased in every experiment, but the effects were decidedly more marked, as a rule, during the first 2 hours after morphin. The maxima decreases in heat production, being 72, 51, 43, 60, 44.75, 55, 85, 84, 23, 32, and 67%, respectively, or on an average about 58%. The average in the 10 experiments in which the dose was 0.01 gram per kilo was 59.2%. The maxima decreases were recorded in 1 experiment during the first hour; in 8, during the second hour; in 2 during the third hour; and in 1 during the fourth hour. Heat dissipation was also decreased in every experiment, and the maxima decreases were 31, 64, 54, 27, 37, 42, 32, 49, 67, 14, 32, and 29%, respectively, or an average of not quite 40%, while the average for the first 10 experiments was 41.7%. The maxima decreases occurred in 2 experiments during the second hour; in 5, during the third hour; in 4, during the fourth hour; and in 1, during the fifth hour. The fall of heat production sets in sooner, progresses more rapidly, and reaches a maximum earlier than the fall of heat dissipation. The mean depression of heat production was about 20% greater than that of heat dissipation.

The actions of morphin upon thermogenesis and thermolysis can, however, be understood by studying the results of the experiments as a whole, than by considering each experiment separately. If we find the mean heat production, heat dissipation, and body-temperature of all 10 experiments for each hour, and from this data construct composite curves, we obtain a composite picture, as it were, of the typical effects of a dose of 0.01 gram per kilo of body-weight, as shown in the accompanying cut (Fig 1). Examining these curves it will be noted that heat production, before giving morphin, was increased to a trifling extent (0.7 kilogram degree). After giving morphin, it fell 6.339 kg., or 26%, during the first hour; and 8.735 kg., or 36%, in addition during the second hour, thus falling 15.074 kg., or about 62%, or to 38% of the normal in 2 hours. During the third hour an increase occurred of 5.715 kg., and during the fourth hour a further increase of 0.696 kg., leaving heat production at the end of the fourth hour at only 65% of the normal.

Heat dissipation before giving morphin was somewhat in excess of heat production, and was increased 1.08 kg. After giving morphin it fell 2.989 kg., or about 11%, during the first hour; 5.86 kg., or about 22%, during the second hour; 1.367 kg., or about 5%, during the third hour; and 5.143 kg., or nearly 20%, during the fourth hour, the total fall being 14.359 kg., or about 55%, or to 45% of the normal. It will thus be noted that heat production fell only during the first 2 hours, while heat dissipation continued falling throughout the 4 hours, and quite regularly; but it was only during the fourth hour after morphin that heat dissipation was

reduced more than heat production. During the first 2 hours heat production fell about double as much as heat dissipation.

The cause of the decrease of temperature is rendered apparent by a study of the relations of the curves of heat production and heat dissipation, as exhibited in Fig. 1. Before giving morphin heat production was a little less than heat dissipation, causing a fall of temperature of 0.19° . During the first hour after morphin both heat production and heat dissipation fell, the former 26% and the latter 11%, causing the temperature also to fall 0.39° . During the second hour both heat production and heat dissipation continued decreasing, the former about 36% and the latter 22%, resulting in a further decrease of temperature of 1.19° . During the third hour heat production increased, and heat dissipation fell about 5%, but owing to the continued deficit of heat production in relation to heat dissipation the temperature still further declined 0.18° . During the fourth hour an increase of heat production, together

FIG. 1.—The curve of heat production is represented by a solid line (—); of heat dissipation, by a broken line (---); and of rectal temperature by a dotted line (.....).

with the continued decrease of heat dissipation, caused more heat to be produced than dissipated, and as a consequence there occurred a rise of temperature, this amounting to 0.26° . That the marked fall of temperature caused by morphin is due to a lessening of heat production is obvious from the fact that while both heat production and heat dissipation are lessened, the former is affected the more decidedly.

The cause of the decrease of heat dissipation is doubtless owing chiefly to two factors: First, to compensating actions of the thermolytic mechanism to conserve the body-heat; and, second, to a direct depression of the circulation.

The cause of the decrease of heat production is theoretical, and we should not be justified in attempting to reach conclusions as to how and to what extent each structure shared in this depression until after a detailed study of the effects on at least all of the most important metabolic processes, because each tissue that is directly or indirectly affected by morphin has its metabolic activities increased or decreased, as the case may be, and thus takes part in the alterations of the mean quantity of heat produced. Under ordinary conditions, prob-

ably 5% of the total heat production, in the absence of volitional movements, shivering, etc., is contributed by the metabolic processes in the heart and respiratory apparatus, the remainder coming from the other active structures of the body, and varying in quantity from each in accordance with the degree of activity. In two of the experiments, the mean metabolic activity, as shown by heat production, was decreased as much as 84 and 85%, thus lowering the mean metabolic activity of the body to about 15%, or about $\frac{1}{4}$ of the normal. Deducting from this the heat contributed by the circulatory and respiratory mechanism, the remainder is so small as to indicate a state of vitality bordering on dissolution, and one which must of necessity directly or indirectly injuriously affect every function. It would, therefore, seem unreasonable to assume that so profound a depression, apart from any other consideration, is not shared to an important degree by the metabolic processes which are concerned in internal secretion, and with consequent important results.

If the vital centers be partially or wholly deprived of substances essential to their activities, it is obvious that the most important indication in morphin poisoning is not merely to administer specific excitants to the respiratory and vascular centers, but to reach the causes of the depression, and therefore to direct some measures to the processes which are concerned in internal secretion and in repair. In fact, it is more than probable that most of the agents which are, or appear to be, of unquestionable value in the treatment of morphin and opium poisoning have proved so, in part at least, because of their action upon these processes, although entirely unrecognized. Atropin, caffein, strychnin, cocaine, faradization, cold douches, and prolonged very hot baths, will doubtless generally be regarded as the most effective physiological antidotes, and with the exception of atropin each will be recognized as an agent which more or less decidedly excites both special and general metabolism.

As regards atropin, I have already called attention to the fact that clinical, experimental and toxicological data demonstrate clearly that this substance cannot be regarded a reliable respiratory stimulant in morphin poisoning. (*University Medical Magazine*, February, 1891.) Furthermore the results of subsequent investigations not only fully verify this statement, but also show that while in some cases atropin is of value, in most cases it is worthless or positively harmful. Upon the circulation it is also uncertain in its actions, therapeutic doses sometimes increasing the pulse and the arterial pressure, and sometimes decreasing both, etc. The causes of these variations I have also shown (*loc. cit.*). Atropin is claimed to be in therapeutic doses a depressant to the cardioinhibitory apparatus, and a direct stimulant to the heart; a stimulant to the vasomotor center and peripheries; a delirifacient; and sometimes an excitant to thermogenesis, increasing body temperature in this way. There is very little evidence which indicates that this substance is to any marked degree a metabolic excitant. In fact, apart from its cardiac, vasomotor and cerebral excitation, and its direct stimulation of the respiratory center (which may more than be offset or antagonized by the effect of the depression of the pulmonary fibers of the vagi and other factors), it is probable that it is an almost universal metabolic depressant, and that its reputed value in opium poisoning is owing largely to the circulatory and cerebral excitation, coupled at times with a more or less important

increase of the rate or depth, or of both rate and depth, of the respiratory movements.

Caffein is a very general metabolic excitant, and there is evidence which leads to the belief that in opium poisoning, besides its value as a direct respiratory, cardiac and psychic stimulant, it is of indirect value by affecting internal secretion through actions on the nervous, muscular and secretory structures. It increases body-temperature by increasing heat production, and it in some obscure way affects general nutritive processes, allaying the sense of hunger, apparently lessening the quantity of urea formed, facilitating assimilation, and acting directly upon the muscles to increase the activities of their chemical processes.

Strychnin is stated to be a powerful and certain respiratory stimulant in morphin poisoning, but the experimental and clinical evidence is far from convincing, excepting when strychnin was pushed so far that the individual was on the verge of convulsions, and in about as much danger from one poison as the other. Elsewhere (*Therapeutic Gazette*, April 15, 1892) I have shown that when it is given *subcutaneously* to normal dogs, and even in doses so large as nearly one-half the minimal fatal quantity, it is without any specific effect on the frequency of respiration movements. In man, in therapeutic doses, its general tonic influence is simply shared by the respiratory center in common with other structures, and its effects upon the respiratory movements are too feeble to be of any important value in states of depression so profound as in morphin poisoning. That strychnin will, however, powerfully and certainly excite the respiratory center when injected *intravenously* in doses so large as to cause dangerous effects is without doubt. But entirely apart from any direct action upon the respiratory center, suppositious or otherwise, this substance may be of value because of its widespread tonic powers in restoring the normal activities of trophic and allied centers. That it exercises an influence upon internal secretion is indicated in its stimulation of the salivary glands, by the increase of heat production as shown by the rise of body-temperature, and by its favorable effects upon nutritive processes generally.

Cocain is among the most powerful of respiratory excitants. In many ways it is apparently a powerful physiologic antagonist to morphin. It is a psychic, respiratory, cardiac, vasomotor, muscular and secretory excitant; and it decidedly increases body-temperature by increasing heat production. All indications point to its being a very general and potent metabolic stimulant.

Faradization, is, as is well known, an excitant to both special and general metabolism.

Cold douches decidedly affect the metabolic activities of the skeletal muscles, increasing chemical tonus and heat production.

Prolonged very hot baths tend powerfully to reflexly excite the respiratory center by actions upon the cutaneous nerves, and to restore the normal temperature of the body, and thus favorably influence all forms of metabolic processes.

While it would be futile to contend upon a basis of such generalities that the antidotal values of these several agents (not considering atropin) are due in any large measure to their actions upon the metabolic processes that are concerned in internal secretion and in repair, it seems equally futile to assume that these processes are not depressed, and therefore take part directly and indirectly in the causation and intensification of

the lethal symptoms; but what degree of importance is to be attached to the consequent effects of this depression upon the respiratory and circulatory mechanisms is of course problematical.

This subject opens a wide and laborious field of research, and considerable experimental work along different but cooperative lines will have to be done before we can hope to obtain data of sufficient scope to enable us to reach satisfactory conclusions. Nevertheless, it must be admitted: First, that the profound depression of general metabolism, even by sublethal doses, together with the probable involvement of the processes concerned in internal secretion and in repair and their consequent effects, must be considered among the important factors in the treatment of morphin poisoning; second, that further research will probably show that we have in this depression an agent in explaining, in part at least, the values of certain physiological antidotes, and, on the other hand, the ineffectiveness of others which upon theoretical grounds should prove of signal power; and third, that if a means be found to restore the normal processes concerned in internal secretion and in repair, the counteraction of the direct actions of morphin upon the metabolic processes which are specifically engaged in the discharge of respiratory impulses will probably be accomplished with far less difficulty than heretofore experienced.

In the near future I will supplement this article by the results of further research.

PARESIS SIMULATING BRAIN TUMOR.

By WHARTON SINKLER, M.D.,

of Philadelphia.

Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases

It is familiar to everyone how patients suffering from paresis often have symptoms which resemble so closely those which arise from localized disease in the brain, that one can scarcely believe that there is not some gross lesion present. The convulsive seizures which occur as a late symptom of paresis frequently begin in or may be confined to one arm, and one sometimes sees in a paretic almost typical Jacksonian convulsions. As the disease progresses, the convulsive movements may involve the entire side, and consciousness is often completely lost for minutes or hours. After a seizure there may be more or less complete paralysis in the arm or whole side for several days, and in cases in which the hemiplegia is right-sided, there may be aphasia, which is generally transient but may be more or less permanent. When the mental and other symptoms of paresis are not pronounced, it is difficult to convince oneself that there is not a tumor or other gross lesion of the brain present. The following cases are illustrative of the above statements:

Case 1.—W. A. consulted me on September 1, 1885. He was 35 years of age and gave a history of syphilis. The family history was bad; three brothers were or had been insane, and one of his uncles was alleged to have had softening of the brain. About a month before he saw me he awakened one morning with violent pain in the left eye. A day or two later he noticed that he had double vision and consulted Dr. Oliver, who referred him to me. Under the use of potassium iodid and faradism to the external rectus, the pain and double vision disappeared in the course of a few weeks. I did not see the patient again until September, 1887, two years later, when I was sent for to see him on account of two epileptiform convulsions which he had just had. He had

had 3 or 4 seizures of a similar character during the few months previous, each followed by severe headache but no paralysis. When I saw him he was incoherent, the speech thick, and he was unable to express his wants, but there was no paralysis. In 24 hours he entirely recovered. Two or three weeks later he had an attack of excitement brought on without sufficient provocation. He had delusions of persecution and at the same time some grandiose ideas. On January 7, 1888, he had 4 convulsive attacks; following these he was aphasic and there was ptosis of the right lid. By January 24 the aphasia had almost entirely disappeared, except that he occasionally misapplied a word. On March 20 he had another convulsion. The face was drawn to the left and both arms were violently convulsed. This attack was also followed by aphasia. Convulsions now occurred at intervals of from one to two weeks. The strength of the right side was decidedly less than the left, but there was no distinct paralysis. The ocular conditions were as follows: At the first examination there was paresis of the right externus and compound myopic astigmatism. January, 1887, Dr. Oliver reported that "Fields of vision were normal, although those of the left eye were somewhat reduced in area. The eye-grounds gave marked evidences of regressive neuro-retinitis and this was more pronounced upon the left. Upon individual exposure, the left pupil was the larger, although conjointly both became equal. In associated action the irides were freely mobile to light stimulus and accommodative reaction. A slight paresis of the right externus could be made out."

About the end of May he had another seizure, after which the entire right side was paretic for 8 hours, and the aphasia was more marked. From this time onward the patient's condition grew worse. His mental state deteriorated and he had periods of excitement which caused him to become violent. He was finally admitted to the Pennsylvania Hospital for the Insane, where he remained until his death, which occurred 3 months after his admission. An autopsy was made in which the only lesions found were those of paresis; that is, the pia arachnoid was opaque, and there was an unusual amount of subarachnoid serum, but there were no gross changes to be found anywhere in the brain. Through an accident the brain became unfit for microscopic examination.

CASE 2.—A. J. E., aged 32, married. Consulted me October 6, 1898. He never had syphilis and had always been temperate and correct in all of his habits. No history of any serious illness. His occupation was that of a bookkeeper, and he had previously been for a time employed in a drug store, but had to give up the work because he was not strong enough. He is the father of 5 children, all of whom are healthy except the youngest boy who is 2½ years of age, and who was born after the present illness of the patient began. The child is a deaf mute and is backward in every respect. Four years ago the patient got into an altercation with a man, who struck him a violent blow on the left side of the head, just below the ear, and he fell, striking against a bulk window and injuring the right side of his head. When he got upon his feet he was again struck on the side of the head by his assailant. He was stunned and dazed when he got home, but there was no external injury. For about 2 months after this he had a noise in the right ear and was somewhat deafened. He then saw his doctor about it. He was not otherwise affected, except that his wife thought he was more irritable than usual. In the autumn of 1897, about 3 years after the injury, he seemed to get worse. There was a tendency to shaking of the hands, his speech became hesitating and his memory was impaired. He continued his work, however. In May, 1898, he suddenly had a sense of numbness in the right arm, which extended to the head and also to the leg. The attack lasted about 15 minutes, and after this he seemed as well as before. He had another similar attack 2 months later and about 3 weeks before seeing me he had had a third attack. In addition to the numbness in the arm and leg and drooping of the lid, there was inability to swallow and thickened tongue. He was not unconscious during the attacks, but after one he always seemed worse than before; he dragged his leg more and seemed generally feeble.

On examination it was observed that the expression was vacant. There was a tendency to drooping of the left side of the mouth and the speech was slow and inclined to be

scanning, his memory was poor, sleep variable, there was no nystagmus, pupils equal, knee-jerks markedly exaggerated but no clonus. The patient's mental condition was evidently below par, although he had no delusions. There was a tendency to tremor in the hand when it was used, and in walking his whole body was moved stiffly. He could whistle and there was no marked tremor, but his tongue trembled when it was protruded. He had no headache, and there was no loss of power in the arm, but he was inclined to drag the right leg in walking.

The patient's mental condition grew worse from this time. He became delusional and at times was greatly excited so that it was difficult to manage him. He finally lost strength and fell into a condition of dementia. He died July, 1900. The brain was sent to me for examination, and I referred it to Dr. Spiller, who found no gross lesions, and who has kindly made the following report of the microscopic examination:

"Sections from the left paracentral lobule stained with a nuclear stain show distinct round-cell infiltration of the pia. Round-cell infiltration is also found about the vessels within the brain-substance, but does not extend beyond the perivascular spaces. Numerous spaces, small and usually round, are found within the white matter beneath the cortex. It is difficult to say whether these are caused by a gas-forming microorganism, or are the result of degeneration of nerve fibers. No microorganisms can be found by deep staining with thionine. These spaces are far more numerous in the white matter of the brain and in the medulla oblongata than they are in the cerebral cortex, and are not separated from the surrounding tissue by a distinct wall. Many of the perivascular spaces are much enlarged. It is difficult to express an opinion in regard to the number and condition of the nerve-cell bodies and of the medullated fibers, as the method employed for hardening the tissues prevents the proper staining with thionine and Weigert's hematoxylin. The above description applies also to sections from the left upper ascending frontal convolution, from the right frontal lobe and from the medulla oblongata. The condition is one of meningoencephalitis."

OPERATIVE TREATMENT OF TUBERCULAR LYMPHOMATA OF THE NECK.*

By PRESCOTT LE BRETON, M.D.,

of Buffalo, N. Y.

NATURE has provided a wonderful barrier to certain diseases and infections in human beings by the elaborate system of lymphatic channels and nodes throughout the body. Due warning is given of an invasion of septic or other processes by the swelling, pain, and tenderness occurring in the glands and noted by the patient. Certainly no surgeons think of removing such able sentinels so long as they preserve their usefulness and are more serviceable than damaging. When, however, the infectious process overcomes the resistance met with, the surgeon must interfere. As regards operation in the case of tuberculosis of the lymph nodes opinions are at variance. Schleich, of Berlin, advises a conservatism almost unsurgical, because of unsatisfactory data as to surgical treatment. Wheaton states that the protection afforded is so perfect and so extensively exercised that removal of such a help to health is often a crime. Horace Grant, after quoting these men in a recent article, has summed up the matter and meets the objections offered.

1. Although there is a loss of protection for a time, the remaining glands and newly-formed lymphatic channels soon perform an extra duty, just as one kidney will do the work of two, or as one part of the brain will do the work of a part previously excised.

* Read at a meeting of the Surgical Section of the Buffalo Academy of Medicine, February 5, 1901.

2. The difficulties of complete removal in competent hands are never insurmountable.

3. Dissemination of tubercle bacilli may be prevented by careful dissection and cleanliness during the operation.

We may add to these statements that operation is indicated because general infection does occur in a large proportion of cases of tuberculosis of the cervical glands. Van Noorden, quoted by Dowd, found that of 149 cases whose histories had been traced for 3 years or more, 28 died of general tuberculosis and 14 others had pulmonary tuberculosis, but were alive at the time of the report.

Treves, in his monograph, written as early as 1882, had found excision, scooping and cautery puncture the best treatment.

Certainly the general trend of opinion among surgeons in this country, as evidenced in the latest editions of Da Costa, Roberts, Stimson, etc., is towards radical operation in all cases that have withstood medical treatment.

The great frequency of cases in which lymphomata of the neck appear renders the subject an important one. In children tuberculosis starts most often in this region and assumes various types. Watson Cheyne in the Harveian lectures in 1899 gives the most practical classification according to clinical characteristics and indications for treatment.

1. Cases in which the glands remain hard, small and movable, with no marked tendency to softening or matting together. As long as the glands are quiescent they may be left alone and medical treatment alone instituted.

2. Cases in which the glands enlarge steadily or at intervals until the whole side of the neck is involved in a mass of glands, some free and others matted together, and in all stages, from those which are fleshy in appearance to those which are cheesy and suppurating. Here medical treatment is contraindicated and surgical intervention should be prompt and thorough, consisting in complete excision.

3. Cases in which the inflammation is very active. The glands enlarge rapidly and soon suppurate while fresh glands become involved. Periadentitis is early, and unless the case is operated upon, abscess after abscess forms, and numerous ulcers remain. Again excision is indicated. Although many surgeons are content with scraping, excision is the better plan, with removal of capsules, fat, and neighboring glands.

4. Cases in which there are unopened abscesses, and these may be subdivided according to the position of the abscess. If 1 or 2 glands only enlarge and suppurate, by making an oval incision over the mass and dissecting outside the abscess, one may often enucleate abscess and glands in toto. If the abscess is accidentally opened while dissecting, the pus should be washed away immediately. Where the abscess has broken through the deep fascia and undermined the skin, it is sometimes wise to incise and drain 3 to 4 weeks and then operate, rather than excise the thin skin over the abscess and leave a large scar that may stretch.

5. A series of long-standing cases in which ulcers and sinuses remain with remnants of broken-down tubercular tissues and glands at the bottom. The treatment is either excision or scraping, with the application of iodoform or carbolic acid.

The most important rule to remember in excising these cervical glands is to remove not only the glands, but their capsules and other surrounding tissue, in

which are often small glands already infected. In other words, to go wide of the disease as in operating upon malignant growths. This produces the best results, the cleanest wound, and the quickest healing. Cheyne is the most ardent advocate of a complete and radical operation, leaving the least chance of recurrence. Hartley considers it best to identify the chief structures in the neck and dissect them from the mass, rather than to dissect the mass from them. The operation must be planned beforehand and carried out systematically with an incision large enough to expose the field and allow complete extirpation without cutting important structures.

Numerous incisions have been devised. In the submaxillary region an incision similar to Kocher's for excision of the tongue is the one preferred. If only a few glands are involved in the anterior triangle a straight incision in front of the sternomastoid will be sufficient. In the posterior triangle a straight incision behind the sternomastoid or an incision running down behind the sternomastoid and curving backward above and parallel to the clavicle. When the glands in both the anterior and posterior triangles are enlarged some surgeons incise parallel to the muscle both in front and behind and dissect, lifting the muscle up from its bed. The incisions of Hartley and Dowd are the best and afford more room, each being followed by the cross-section of the sternomastoid. Hartley formerly used the S H and T incisions but abandoned these in 1897 for the following: Beginning just below the mastoid process in front of the sternomastoid, incise along the anterior margin of the muscle to its middle point, alter the direction to run downward to a point one inch above the sternoclavicular articulation, then curving laterally with a rounded angle, pass across the posterior triangle till a line joining the two extremities of the incision passes behind the posterior margin of the mass. Dowd's incision is the reverse of this in position. Starting from under the lower jaw, running backward to the mastoid and downward along the hair border, the incision is continued as far forward and downward as the extent of the disease renders it desirable. The scar resulting from this is the least noticeable and is not liable to stretch.

Having incised through superficial fascia and platysma, the flap is dissected back. The external jugular vein is tied above and below and any superficial glands along its course are removed. The sternomastoid is now cut transversely below the exit of the spinal accessory nerve and its ends reflected, in this way uncovering the great vessels from the mastoid process to the clavicle. Milton, quoted by Dowd, reports two cases of torticollis following this muscle section, but no other ill effects have been seen, as many surgeons testify. The writer has cut this muscle several times and reunion and return of power have resulted. The key to the situation is to locate the internal jugular vein at the lower end of the wound and follow it as one finds and follows the axillary vein in the axilla. If the disease is continued to the root of the neck, slow and patient work is insisted upon to avoid the pleura and other important structures and especially the thoracic duct on the left side. Having located the internal jugular, by blunt dissection, aided by snips with curved scissors, the contents are enucleated en masse. In managing the tumor violent tearing of the nodes should be avoided and the tumor-hook must be prevented from puncturing suppurating foci and spreading pus over the wound.

If periadenitis is present and the glands are adherent

to the internal jugular, it is best to ligate it and remove it with the glands. The dissection is facilitated and no harm is done to the patient. Watson Cheyne says: "Probably in the majority of cases—in all cases where there are sinuses and practically in all cases where supuration is present—I make a point of dividing the vein between two ligatures and taking it away along with the mass of glands." If the vein is removed the superior thyroid, lingual, and facial veins are met with above and must be ligated. A final ligature is applied to the internal jugular at the upper end of the wound. The descendens noni is recognized and saved. As the mastoid process is neared the spinal accessory is looked for at its entrance into the sternomastoid and followed upward, separating the glands about it. Then the glands under the mastoid may be freed, care being taken not to cut the facial nerve. Rarely there are glands beneath the common carotid which, when enlarged, are removed. After defining the spinal accessory at its exit from the sternomastoid and freeing it, the posterior triangle can be cleared. The entire field should now be clean. The sternomastoid is sewed with catgut. If Hartley's incision is used a puncture at the base of the flap is made and a small drainage tube inserted to remain 48 hours. The flap is sewed in place unless pus has smeared the wound, in which case 1 or 2 wicks of gauze may be added at the corners of the incision. If sinuses have been present they are scraped out before the operation is begun and the edges cut away.

The lowest branch of the facial, running below and parallel to the lower jaw, is often cut. This causes a temporary drooping of the lower lip near the angle of the mouth, but need cause no alarm. The superficial branches of the cervical plexus are usually injured, resulting in anesthesia of the skin supplied by them. The deep branches can be avoided. The writer has seen one case in which the thoracic duct was cut. Chyle flowed freely for about a week, then the discharge gradually ceased, pressure being applied over the discharging area. A frequent use of hot saline solution in the wound clears it of blood and causes the tissue to stand out in bold relief. Many small vessels are wounded and it is only by salt-solution that we may secure an unstained field.

Patients stand this extensive operation well, being up and about in a week or ten days. In a series of 7 cases, operated on by the writer, there were no accidents or complications. The writer remembers one case in which the common carotid sloughed through the night after operation, at a point where it was infiltrated with tubercular tissue. The hemorrhage was severe, but a ligature was tied about the artery and the patient lived. In the case of a little girl in which the submaxillary glands were excised, death followed on the third day from what was apparently an ulcerative endocarditis. No autopsy could be obtained.

The ultimate results are encouraging. Dowd gives the following table of cases whose after-histories were followed in most instances for several years.

Total number of cases	309	
Apparently cured	202	65.4%
Living with local or general tuberculosis	57	18.4%
Died of tuberculosis	50	16.2%

Since it has been proved that the bacilli enter, as a rule, through the mouth and pharynx, an important adjunct to the treatment is the removal of adenoids, and hypertrophied tonsils and the care of carious teeth.

Eczema of the scalp, rhinitis and otitis demand attention.

A SKIAGRAPH OF BENNETT'S FRACTURE OF THE METACARPAL BONE OF THE THUMB OR "STAVE OF THE THUMB."*

By JOHN B. ROBERTS, M.D.,

of Philadelphia.

THROUGH the courtesy of Dr. George Thomas Beatson, of Glasgow, Scotland, I am able to show a Röntgen-ray print of this fracture. The injury was accurately described in 1885 by Professor E. H. Bennett, of Dublin, Ireland, but has not attracted as much attention in this country as it should.

FIG. 1.

The fracture occurs obliquely at the base of the metacarpal bone of the thumb on its palmar aspect, detaching a portion of the base of the bone. It runs into the joint between the metacarpal bone and the trapezium. As a result of this detachment of a considerable portion of the articular surface, the metacarpal bone is displaced backward and gives a deformity similar to that of a posterior subluxation. The injury is usually

* Read before the College of Physicians of Philadelphia, February 6, 1901.

FIG. 2.

caused by a blow applied in the long axis of the thumb. The pain causes a disability in opposing the thumb to the index finger and probably to the other fingers. Grasping small objects becomes impossible

and pressure on the ball of the thumb gives pain. The injury is likely to be mistaken for subluxation, sprain, or contusion. It is to be treated by extension and full abduction of the thumb, which should be maintained by a gypsum or other splint. The skiagraphs of Dr. Beatson's case were taken sixteen days after the injury and at the conclusion of treatment. The fracture, until seen by Dr. Beatson, had been unrecognized and had not been reduced.

The attention of the Fellows is called to this injury because it is probable that it is overlooked. I have never recognized the fracture, though the inspection of the skiagraphs calls to my mind an injury of the thumb seen some time ago which was not clear to me. It is possible that it was a case of this kind.

A CAST AND SKIAGRAPH OF THE SO-CALLED SMITH'S FRACTURE OF THE LOWER END OF THE RADIUS.

By JOHN B. ROBERTS, M.D.,

of Philadelphia.

SEVERAL years ago I showed a series of specimens from the Mütter Museum illustrating fracture of the

FIG. 3.

FIG. 4.

lower end of the radius with anterior displacement. There were also shown at that time skiagraphs of such fractures. In a monograph presented to the American Surgical Association in 1896, I recorded a number of instances occurring in my own practice and collected from various sources. Experience in, and study of, this injury have convinced me that it is usually overlooked. Of the five or six cases which I have seen there was probably not one in which the character of the injury was clearly understood by the practitioner who first saw it.

It is a great pleasure, to be able to present to the college at this time a cast and a skiagraph of an old injury of this sort, sent me by Dr. George Thomas Beatson of Glasgow, Scotland. The case was one which Dr. Beatson did not see until a year after the accident. It occurred in a woman of 46 years, who fell from a bicycle. The deformity corresponds with that usually seen, and the skiagraph is an almost perfect representation of the specimen in the museum of the New York Hospital, a picture of which was given in the article to which reference has been made. It is unnecessary to speak of the treatment in full at this time. It may, however, be said that it requires the application of force, often great force, to break up the impaction and restore the fragments to their normal relations. A moulded splint, made of metal, gutta percha, or gauze and plaster of Paris, should then be applied to the palmar surface. In some cases a straight splint may be applied to the dorsal surface instead of the moulded splint to the palmar surface.

ON THE NECESSITY FOR THE ORGANIZATION OF BACTERIOLOGICAL COMMISSIONS FOR THE STUDY AND INVESTIGATION OF QUARANTINABLE DISEASES UNDER THE FORMATION AND CONTROL OF THE GOVERNING AUTHORITIES OF THE COUNTRIES INTERESTED—AN ABSOLUTE NECESSITY FOR THE SCIENTIFIC MANAGEMENT AND BETTERMENT OF MARITIME HYGIENE AND QUARANTINE.*

By HENRY B. HORLBECK, M.D.,
Health Officer of Charleston, S. C.

THE story of maritime hygiene and quarantine is the tale of the closing years of the nineteenth century.

It is the history of one of the great problems confronting civilized mankind, a problem to solve, whose mission it is to protect tens of millions of mankind from the transmission of diseases of fatal tendencies and to permit with all possible freedom the interchanges of commerce, and thus secure international exchange.

When it is considered how absolutely necessary to the well-being and happiness of mankind is the unlimited and unshackled and unchecked intercourse of nations and communities on the great highways of the sea, it will be seen how serious and momentous is the question to be answered. As the civilization and prosperity of the world have advanced, so has the imperious demand been made *pari passu* for the minimization of restraints upon commerce and for some practical solution of the world-wide problem of holding in check and fettering the great leviathans which traverse the oceans of the world.

The maritime hygiene and the maritime quarantine

of the past concerned not itself with the hardships of a 40-day detention; fleets of vessels were kept infecting and reinfesting themselves for this period, this confinement ceasing only when every craft had been subjected to quarantinable disease.

From the quarantine detention of 40 days, which was the recognized period of detention in the past, to the quarantine restraint of 5 days now prescribed is a great leap and a vast progress.

From the sulphur pots of only 15 or 20 years ago to the perfected jacketed steam cylinder is a far greater bound and shows a much greater growth.

These are not simply advances loosening the check-rein that has hampered commercial prosperity and progress, but they are methods that have greatly minimized and lessened the chances and dangers of the introduction of diseases which scourge mankind and desolate the households and habitations of human victims.

These steps of human progress have been accomplished in so short a period of time that would almost seem incredible. It has all occurred in less than a generation of man, and during the official life-terms of some of us who are engaged in the daily mission of protecting our shores from the introduction of dangerous and deadly diseases. With a better knowledge of the diseases most to be dreaded our restraints will be surely lessened, and our ability to protect our shores increased.

The outlook, the standpoint, and the responsibilities of one engaged or charged with the duties of carrying out a safe quarantine vary greatly with his locale. While each and every quarantine official feels to a certain extent the requirement of protecting his community from the advent of all dangerous diseases he feels that there are certain diseases which are to him most important, and to which his community is especially liable and which he must guard against with all his main and all his soul. The health official of one of our northern ports feels every pulse quicken at the reports of cholera and plague.

The health official of our own latitude on the south Atlantic coast of the United States, and to the south of us is never insensible to the notice and warning of the presence of yellow fever, and so around our little world there will be found on the borders of every ocean or sea some plague or pestilence or disease that prevails in that locality with a tenacity and a deadly force that must be accounted with. These diseases demand every requirement that this age of vitality and accountability has furnished and provided for the protection of the people interested.

All of us, therefore, that are engaged in this all-important work must look to such dangerous diseases as may when introduced injure and destroy those with whose well-being they are charged, and all of us, it is to be presumed, have perfected ourselves in a knowledge of the appliances which scientific advance has furnished; so it is not therefore necessary to epitomize what temperature shall be employed to destroy the dangerous cocci, or this pathogenic bacillus, or that perilous spirillum. Our health associations and medical organizations have had papers and papers presented on such matters explaining thoroughly their uses and advantages.

What is the all-absorbing thought in entering upon such an exciting theme or subject as Maritime Hygiene and Maritime Quarantine?

* Read before the Section of Marine Hygiene and Quarantine, Pan-American Medical Congress, February 4, 1901.

We all know that a temperature of 230° F. will surely kill pathogenic bacteria; this much we know, and we can surely and safely use this temperature with confidence, and we have the jacketed steam cylinder to effect the desired result.

We may also use with more or less confidence and belief in their germicidal value certain solutions of certain chemical salts and certain vaporizations which are at our easy command.

We are thus armed and equipped with the materials for warfare, but it is a warfare against an enemy in many cases of which we know but little.

It is the bludgeon's work and not the rapier thrust; and is such work required in all cases?

The dominant, all-important, all-pervading necessity in the work of maritime hygiene and maritime quarantine is a better and fuller and more thorough knowledge of the pathology and of the etiology of the diseases against which our quarantine officials must contend and make warfare.

The all-absorbing necessity is a better and a fuller knowledge of the causes, and we can in no way better further the great and important subject of maritime hygiene and quarantine than by urging upon these earnest gentlemen of this Pan-American Congress the necessity of awakening the public thought and interest among the people they represent towards the more definite and closer study of the diseases which hamper commerce, and which are dangerous to the lives of the communities with which commerce holds intercourse.

We have been following in the wake of ignorance, century after century, until the two last decades.

The discovery and the use of the oil-immersion lens and other mechanical appliances has given us the opportunity of acquiring an exact knowledge of the pathology of the diseases which are ever present and which are ever dangerous.

The exact knowledge of the *raison d'être* of these diseases due to specific origin is imperative, and meantime maritime hygiene and maritime quarantine will never be scientifically fulfilled until this is obtained. To acquire such sure and certain information there must be established Government commissions, arranged for bacteriological research. In every State and in every community where there are diseases that exact constant thralldom to commerce and that are of ever-dangerous importance, there should be established bacteriological stations for constant, unremitting, and continuous work; not that this commission should work for a limited period, and then another commission organized, whose first duty may be to hunt for a lost thread of a predecessor's labors, but an organization of trained bacteriological experts, who shall be so equipped as to ensure a successful investigation, and to continue such labors until the work that has been assigned to them has been brought to a successful termination—*nulla dies sine lineâ*—following the heritage of Lord Bacon: "Its law is progress; a point which yesterday was invisible is its goal today, and will be its starting-point tomorrow."

For two and a half years Dr. Ross, with unflagging interest and persistent energy, though baffled again and again, sought the malarial organization in the mosquito, and he finally found it.

The solution of the cause of the transmission of malaria among the nations of the earth—the certain knowledge—dissipating the superstitions of malaria and malaqua, is of such incalculable importance and benefit

that it should be a beacon-light in all lands and in all countries.

This discovery is the result of well-appointed, well-organized, and long-sustained bacteriological investigation.

Laveran commenced this work in 1889, by the discovery and description of the plasmodium malariae.

It has taken 20 years of constant and assiduous work to fulfil all the requirements, so that full fruition should come to mankind, and today the picture is on the wall.

The culmination of the work has been the success of the procedures undertaken and carried out during the summer of the year 1900, at Ostia. Today it is simply the problem of the destruction of the anopheles mosquito. No anopheles, no malaria. It has taken a fifth of a century of continuous scientific work to accomplish this result.

What of the malaria and the malaqua and the miasms and the vegetable organizations undergoing decay or decomposition with light and heat and moisture relegated to the realms of the shades? Definite knowledge has assumed leadership and physicians and sanitarians are in a position with certain and definite knowledge to give instructions as to enlightened methods for the protection of humanity.

The same work must be done as to yellow fever.

For over two centuries have the nations of the two continents of North and of South America paid tribute to yellow fever.

In a recent issue of the *N. Y. Herald* I find the following report as to yellow fever: "Medical officers in Cuba admit that while considerable has been learned about yellow fever since American occupation began, the laws governing the disease have not been discovered. Major Vallery Harvard, chief surgeon of the division of Cuba, says: 'Yellow fever continues to strike when and where it listeth, regardless of our most reasonable expectation and best hygienic measures. Why the germ should remain quiescent and inactive one or two seasons in the presence of susceptible material and then suddenly become active and virulent is a question still unanswered. The outbreak at Santiago last year was attributed on what appeared to be good grounds to the intensely hot and dry spring, while the outbreaks of this year at Santa Clara and Quemados are attributed on equally good grounds to the unusually heavy rains which fell in April and May.'"

What tons of paper and what gallons of ink have been sacrificed in giving the causes of yellow fever and what is the situation today! Theories upon theories. What exact certain knowledge have we of the etiology of yellow fever? None.

We have, however, great encouragement from the recent investigations of Doctor Walter Reed and his colleagues. Following in the wake of Dr. Carlos Finlay, a distinguished investigator of the city of Havana, Dr. Reed with the aid of the microscope has given us a clue to the labyrinth which has so far baffled all investigators.

Quoting from a recent exchange: "Dr. Reed says the experiments show beyond a doubt that there is no contagion from an infected person or from infected clothing, but that the mosquitoes alone are responsible for the spread of the disease."

What a vision of hope this discovery affords,—that the mosquito (*Culex fasciatus*) is the conveyor of the *materies morbi* of yellow fever. It is a source of con-

gratulation to one charged with the great and grave responsibilities attaching to the guardianship of the public health in a great extent of territory. What an encouragement!

Only one having such duties and living in a community susceptible to yellow fever can realize the benefit of such a boon. With the exclusion of the mosquito from the patient the dangers of the transmission of the disease, if the idea proves correct, are *nil*. This solution, that the mosquito is the factor in the etiology of yellow fever, explains many interesting facts: its presence and its absence in various communities, the immunity enjoyed by some and the prevalence of the disease in others, as the mosquito may be in the ascendancy, infecting herself and conveying the poison from one patient to another person.

There is at present, at this period, no known fact established and recognized and accepted as to the specific origin of yellow fever and its methods or modes of transmission.

What has the maritime hygienist or quarantine officer to do? Do as his forefathers have done for generations—proclaim nonintercourse. Certain detention for at least 5 days after disinfection—a sort of empirical quarantine formula.

We are holding our session in the city of Havana, where yellow fever has been more or less present for two centuries, summer and winter, and, judging from the records of the past summer, its inhabitants are as powerless to stay its ravages as they were when the holocaust began—and they have folios and folios to consult as to maritime hygiene and maritime quarantine. Is it not, therefore, becoming in us and proper to send forth to the inhabitants of the North and South American Continents from this Pan-American Congress our urgent solicitation and recommendation that the different governing and representative bodies have such investigating bacteriological commissions organized as we have indicated?

It surely does not want a lurid pen to tell of the tens and tens of thousands who have been victims and whose homes have been made desolate. It does not require more than the recital to tell of a great commerce paralyzed again and again.

It is not a distant past to recall the tragedies and horrors of 1878 in the Mississippi Valley, costing 16,000 lives and \$200,000,000 of money. These facts are known to us all and require but the reminder to bring up to us the picture of the desolations that follow upon such visitations.

And as to yellow fever so to all other diseases which come within the purview and care of officials charged with the administration of maritime hygiene and maritime quarantine.

Without a scientific knowledge of the etiology of plagues and pestilences there cannot be a scientific administration of maritime hygiene and quarantine.

It is our belief that the good health, safety, betterment, and happiness of mankind require that constant effort should be made by each government represented in this Pan-American Congress to establish properly equipped bacteriological stations for the investigation of dangerous and fatal diseases, so that quarantine officials may have such exact knowledge that they may scientifically fulfil their duties.

Sir Dyce Duckworth has been appointed Consulting Physician to the Italian Hospital, Queen Square, London.

ALBUMINOUS NUTRITION AND NUTRITIOUS ALBUMEN.*

By ALBERT BERNHEIM, M.D.,

Instructor in Diseases of the Stomach and Intestine in the Philadelphia Polyclinic and College for Graduates in Medicine.

By the above title Dr. Finkler, professor in the University of Bonn, read a paper before the Ninth International Congress for Hygiene and Demography at Madrid, Spain, April 10–17, 1898. In this paper Finkler discussed elaborately the great and absolute necessity of providing man, in order that he be able to work and to exist, with a food that will yield muscle and with the muscle, strength; strength of body and indirectly strength of mind. At the same time he comes to the conclusion in accordance with many investigators and in contradiction to views, formerly and partly now regarded as valid, that albumen alone is the supporter of the muscle-substance; he quotes Pflüger, by whose exact and accurate researches the maxim has been established, that the albumen is the nutriment of the first order, and whose thesis is: "Full muscular energy though fat and carbohydrates being absent, no muscular energy without disintegration of albumen. Albumen can perform all the work. The materials of the second order, however, the fat and the carbohydrates, are by themselves never able to sustain life; all work of life can be performed by albumen alone, while no other material in the universe can do it. The integral ingredient of the living and working cell is the albumen, indeed often the only organic part of it."

Dr. Finkler gives the daily amount of raw albumen:

1. For hard-working man.....145 grams.
2. For moderately working man 96 grams.
3. For moderately working woman... 61 grams.

Supposing the man's weight to be 65 kilograms and the woman's weight to be 55 kilograms, the daily amount of raw albumen for each kilogram would be:

- For 12.23 grams.
- For 21.48 grams.
- For 31.11 grams.

In the rations of the armies of 12 countries, he finds the average amount of raw albumen as follows:

1. In times of peace117.92 grams.
2. In times of war130.49 grams.
3. In the navy on sea duty148.03 grams.

But the difference between the ingested albumen and the albumen really consumed in the body is great. In every food mixture a certain part of albumen will not be resorbed, that is, it is called indigestible. The correction for this uselessly ingested albumen is of the greatest importance. Of course there are many points to be considered as to this correction, which may offer difficulties, such as the individual percentage of the resorbability of each food, and the mixture of the various nutriment for the meals and particularly the individual disposition of man, perhaps too the training and habits.

There are, however, to a certain extent, a few hints for this correction. By frequent researches the value of the resorbable albumen of some of the main kinds of foods, such as bread, meat, leguminous plants and vegetables has been found.

* Paper read at the meeting of the Philadelphia County Medical Society, January 23, 1901. Re-read on invitation before the North-east Medical Association, January 25, 1901.

On the average we must subtract 5% from the animal albumen and 35% from the vegetable albumen; at the same time man takes about one-third of the food from the animal stuffs and two-thirds from the vegetable stuffs:

Correcting according to that the above mentioned figures we get:

For 1.....	108.08	digestible <i>i. e.</i> , resorbable albumen.
For 2.....	72.00	" " " "
For 3.....	45.00	" " " "

And from the same standpoint for the armies of the 12 countries:

1.....	88.19	digestible <i>i. e.</i> , resorbable albumen.
2.....	100.97	" " " "
3.....	108.00	" " " "

Only the resorbable albumen will be used for the repair of the body; the not resorbable is a waste in the body in regard as to the work to be performed as well as to the money value.

By further investigations Finkler finds that per kilogram and 24 hours 1.73 grams albumen are necessary for a hardworking man, for a moderately working man 1.42 grams; therefore for a man of 65 kilogram body weight:

When hardworking	112.45.
When moderately working.....	92.45, and that only resorbable albumen.

For the hard-working man the defect shown is 3.6 grams, or 3.2%, of the albumen.

For the moderate workingman the defect shown is 20.3 grams, or 22%.

By the same figuring, the ration of the armies in times of war compared to the food of the hard-working man, has a defect of 12.35 grams of resorbable albumen, or 10.16%; the sailor on sea duty 3.6 grams, or 3.2%; and the soldier in time of peace 24.70 grams, or 20.31%, while the albumen in time of peace amounts to 7.2 grams, or 6.4%, above that of the moderately working man.

A remarkable and well-known fact is that the lower social classes have to suffer most from the deficiency of albumen, a fact which is caused by the proportionately more expensive albuminous foods. It is true, records of inquiries from 1853 and 1891 show an improvement to a certain extent, and that in all classes. The difference between the poorest and richest class is 40.0 grams of albumen, whereby not even the richest class reaches the absolutely necessary amount of proteids.

1. The proportion of the daily consumption of albumen in 4 classes, differentiated as to pecuniary circumstances, is 100:117:153:159.

2. The animal ingredients of the food were in the proportion of 100:135:180:236.

3. The total amount of food was in the proportion of 100:111:129:139.

The comparison of these figures shows that the prevailing need is not the fulness of the dinner-pail in order to fill the stomach, but to provide the body with the necessary amount of the best nourishment, namely albumen, the material most suitable for the reproduction of flesh and muscle-substance. Corresponding to the instinctive want and the social conditions improving, first the consumption of animal food increases, then the consumption of albumen in the whole, and but as third the total amount of food.

A question not to be neglected arises. Can the

take-in of albumen not be reduced and be replaced by antinogenous food?

Many investigators believe that this can be done, and perhaps it can be done under certain circumstances and to a certain extent.

But what happens if the amount of albumen is reduced? The first thing is that the organism begins to economize by reducing the metabolism of the body albumen, and conforming to a lower metabolic equilibrium.

Maybe it is possible that for a short time work, that has to be done by albumen, may be performed by antinogenous food, but only for a short time; when less albumen is introduced into the body, the muscle-substance will be reduced in weight, and that very soon and very considerably; the result of it is a hunger for albumen.

If in man, when hard-working, but a small amount of albumen, and a large one of fat and carbohydrates, are disintegrated in the metabolic process, we must not conclude that its reason lies in the large amount of fat, but in the small amount of albumen disposable; this means that either simultaneously less albumen is present in the food, or that on account of a previous reduction of the body albumen, the food albumen must be used for repairing the muscle-substance before a normal level of the disintegration of albumen for the sake of working can be reached. This fact is markedly pronounced in the growing persons, in convalescents, and in persons recovering from hunger.

It is particularly the fat that has been supposed to have the capability of reducing the disintegration of albumen, but at the same time the concession has been made that this fact is not markedly evident when a large amount of fat has been ingested along with a small quantity of albumen. But under such circumstances, in case of subnutrition, the efficiency of fat to save albumen would be just the real desideratum. If large amounts of antinogenous foods are introduced, while the amount of albumen is reduced, these antinogenous foods are expected to perform anything and everything in the body; *muscle work*, however, will not be performed if the above-mentioned maxim of Pflüger is correct, namely, that the muscle consisting of albumen performs its mechanical work through the anabolism of albumen, but never through that of fat or carbohydrates. Under these conditions less work will be performed; for the laborer, moderately nourished with smaller amount of albumen, is not able to perform hard work, because for this purpose he needs the largest amount of albumen, as shown above. With a deficiency of albumen, the body is forced to conform to a lower standard of proteid metabolism. This lower standard is unavoidable in persons who are continuously deprived of the full amount of nutritious albumen so necessary to them. Finkler says that this fact is markedly exhibited by the proof—that the majority of men who have hard work and but scarce nourishment, grow prematurely old and soon become exhausted, a fact which is daily observable.

It is true, certain amounts of fat or carbohydrates furnish a corresponding number of calories as a proportionate amount of albumen does, but there is a deception in our belief that the one can replace the other for any length of time, or even continuously. For man of the present day, in his strenuous struggle for life, the indispensable amount of albumen must be provided for; it cannot be reduced unless the enduring

ability of the worker or the continuance of the full amount of the body albumen will be reduced. Not only the provision of albumen at all, but also the equality of the daily ingestion of albumen is necessary. In the course of the 7 days of a week Finkler found a difference of from 30% to 40% between the smallest and largest amount of the digestible albumen; physiological research has shown that under such circumstances the inequality in the ingestion of the albumen becomes rather a waste of this material, because the superfluency of the one day will not be used up entirely for the benefit of the body, and will not by any means make up for the deficiency of the other day.

Another point to be considered in regard to the food is the digestibility. The loss of the proteids in the bread is about a third of the whole amount, in the legumes about the half. It is true, a proper preparation of this kind of food will help a great deal for the digestion, but nevertheless a large part of the albumen will not be used, and this unused albumen proves a fertile soil for putrefaction, which when continuing for a longer time may result in disturbances of the alimentary canal and further of the whole body.

Last but not least in our times of social revolutions is the question of expense. It is known that those nourishments containing the most nitrogen and being the most digestible and most relishing are the most expensive ones; and since mostly the less well-situated people have to perform the hardest manual work, they will have to come to an ever increasing lower condition of wealth and work. The rich people have less manual work and more nourishing food, the poor people more work and less nourishing food.

How to amend these conditions? Fish, very nourishing, pretty well digestible and not too expensive, may be put down to a greater extent upon the daily bill of fare, but it needs training of the people for the daily use of fishes (besides the best ones are again the more expensive);* creamery products (cheese) are good and may be furnished rather cheap, at least in country districts; but the preservation of milk and cheese has its limits. Vegetable albumen, particularly legumes, may be thought of in this respect, but the digestibility or rather indigestibility becomes a hindrance and besides they are not cheap, or at least not cheap enough to be general food for a large population.

Many and various investigations have shown that on an average 60% of all household expenses have been spent for the food, and the albumen of the food costs more than the half of the food.

There remains the necessity of furnishing good, resorbable, and cheap albuminous food.

*In this place I wish to say a few words on fish diet. Many may regard the albumen originating in fish-meat as a disadvantage, as the fish is considered an inferior food from the social standpoint. I cannot admit this. Where fish-food is plenty the people like it not only as a nourishing food, but also as a delicatessen, especially where the fishes are prepared in a sensible manner. Fried fishes are certainly not preferable to the plain boiled fish. That fish-meat is proportionately cheaper than butcher's meat is well known, particularly as it is more easily digested. Let us hear what Dr. Keen has to say about fish diet.

Fresh fish is abundant and cheap in almost all parts of our new tropical possessions, and it is somewhat surprising that the recent authority for the issue of this cheap, excellent and wholesome variation of the meat ration is not more taken advantage of.

I am informed that the men eat it gladly when issued. Conservatism, which is so characteristic of the military service and in matters of food, of the Anglo-Saxon race, together with slight administrative difficulties which with practice would disappear, seem to be the causes of its comparatively limited use at Columbia Barracks. It has, however, been more regularly used at other posts in this department.

Routine is dear alike to the commissary-sergeant and company-cook, and these two important persons have more influence than is generally recognized in deciding what shall go into the company kitchen. When the greater trouble and labor to the latter in preparing and cooking fish is considered, as well as the fact that the fish ration is less than that of meat, the absence of fish from the bill of fare, where its use is optional with company authorities, is largely explained. Being a less satisfying food than beef, and the waste-heads, tails, entrails, etc., being greater than the proportion of bone in beef, being sometimes as much as

Can such food be furnished?

Of late years, all the scientists, hygienists and social economists have looked out for such a food; only recently the newspapers were full of a report how the president of the Chicago University would endeavor to show how to live on 15 cents a day; the United States Government has employed scientists to make researches as to the value of foods and drinks; not only in America, but also in Europe the governments are seeking for the best methods of feeding large masses, be it for the inhabitants of prisons or for the soldiers in army and navy. Experiments have been tried; have they been successful? Remember the preserved meats, the canned meats and vegetables! Can we say that they are accompanied by success?

Many manufacturers, many packing houses have endeavored to furnish the long-desired foods. It was a great progress when meats could be preserved and shipped all over the world. When the experiments were tried to furnish meat in a well digestible liquid or powdered form, were these experiments really successful? An unprejudiced mind has to say "No."

Some of the foods have been cheap, but they do not keep as well as to be fit for the human body; other foods would be fit for the body, but they are expensive; they are either luxuries for the rich or drugs for the poor; many are nutritious, keep well, but they are on account of the high market price only medicine for the sick, and often if they should be continued, only for the rich sick.

Finkler,¹ after long and many labors and studies in the laboratory of the University of Bonn, was the first to succeed in obtaining a food which has all the requirements of a proteid food as it should be. He made a food:

1. That has the greatest amount of albumen possible, up to 99%.
2. That is digestible up to almost its entire weight.
3. The amount of which can be made equal for each day.
4. That keeps well indefinitely in all climates.
5. The flavor and taste of which does not interfere with the palate of man in combination with other food.
6. The price of which is the lowest possible.

The proteid made by Finkler consists of the digestible albuminous parts of meat, fish and legumes, is odorless and tasteless, of a light-yellowish color, and presents a very fine, sandy powder.

The proteids, as a rule, possess the qualities of solution and coagulation, a fact through which they may be separated from the other ingredients of the food; at the same time, however, they have disagreeable qualities of being closely combined with many substances,

35%, no reason is known why the ration should be less than that of beef, viz., 20 ounces.

Fish is largely eaten by all tropical races near the source of supply, and is undoubtedly less stimulating and more easily digested than butcher's meats. For this cause, and to secure variety, fresh fish, where obtainable, should be used twice a week, no savings being permitted.

The issue of the meat components at Columbia Barracks, Cuba, for 185 consecutive days has been as follows:

Fresh beef	124 days
Mutton	10 days
Bacon	47 days
Fresh fish	1 day
Other issues	13 days

Which shows we had the monotony of the issue, the only important variant being the undesirable bacon.

A certainly more desirable issue, and one apparently permitted according to the paper ration, would have been, for example, somewhat as follows:

Fresh beef	100 days
Fresh mutton	7 days
Fresh fish	8 days
Other issues	15 days

A saving of two-fifths of the fresh meat being authorized.

As fresh fish is quite cheap at Havana the difference in cost would have been immaterial.

such as fat, coloring matter, odors and flavors, the separation from which is a very difficult task. According to the origin of the albumen there are different methods for obtaining the digestible albumen.

It is one thing to gain the animal albumen and another thing to gain the vegetable albumen; but the purification of the albumen of various origin has been done after one uniform method. The fatty and extractive substances, when securing the albumen of animal origin, must be brought into such a condition that they can be extracted, and especially is it necessary that all and even the smallest fat globules are removed, else after a very short time the muscle fibers will acquire a particular disturbing odor or taste. Besides the use of ether for extraction of the fat, the muscle fibers have to be treated by substances which allow peroxid of hydrogen to penetrate into the interior of the fibrillae in order to decompose the fat; simultaneously the albumen will be softened without being turned to albumoses or peptones. It is not enough to cover the odor or taste of the albumen with certain substances, as such experiments will not yield a permanent result. Perfectly pure albumen it must be, if it shall have the qualities of keeping for a longer time and remaining free from any disagreeable odor or taste.

In order to obtain the pure vegetable albumen we must be able to remove it out of the cells of the plants. The conditions are not easy because, first, the cells have to be broken mechanically, and then the various albuminous substances react differently in regard to their solubility in water, alcohol, and various other salt solutions. In extracting fat from plants it may happen that simultaneously the albumen is extracted also; the difficulties are especially great in manufacturing the albumen in large quantities; and this has to be done for the sake of the uniform qualities and the expenses. But they succeeded in this respect too. In the laboratories, of course, it is less difficult to obtain small quantities of pure albumen than in factories. For the sake of cheapness the choice of materials to be used for the manufacturing must be limited, and for the purification we have only the resources of water of various temperature with weak additions of alkalies and acids, of oxidizing and reducing substances.

Among the different contaminations of the albumen are not the least ones the coloring matters, though even the pure albumen may not be entirely white, but according to the temperature and method of drying may have various hues of yellow. For instance, the removal of the coloring matter of albumen gained from the blood of slaughtered animals is, as a rule, pretty circumstantial and expensive. To prevent this, a special method was needed and was found in the oxidation of the blood-coloring matters by means of peroxid of hydrogen. If a sufficient amount of this substance is used, you will succeed, by keeping the albumen at a boiling heat, in destroying the coloring matters and along with them the odorous and flavoring substances, so that the end product will be an absolute sterile and pure hematic albumen. This success depends largely on certain circumstances; thus, it must not be forgotten that fresh blood will decompose peroxid of hydrogen, so that in order to become discolored, it must first be prepared in such a manner that its oxyhemoglobin will be altered. Another point is the fact that when free alkali is present the albumen itself would be decomposed.

Finkler, in order to prove that all injurious contami-

nations of the albumen have been destroyed by the methods employed by him, had, in his laboratory, frequently mixed bacteria as well as bacteria cultures with the toxins contained in them to the raw materials, and at the end of the manufacturing process experimenting on animals convinced himself that the albumen was entirely rid of the poisonous substances in question.

The product recovered from the various materials is an albumen insoluble in water. In the greater majority of the cases such insoluble albumen is preferable to soluble or predigested proteids. Certainly in the healthy person and in the greatest number of the sick, too, we need not a totally or partially digested food; on the contrary, by furnishing such food for a longer time we rather put the individual into a condition not beneficial at all; for by doing so we take from him the work which the stomach and intestines must necessarily perform for the maintenance of their respective functions. Of course, there may sometimes be circumstances where a soluble and predigested food has its place, particularly in a certain number of diseases in which the alimentary canal has lost its power of action.

Finkler made it a special point to remove the gelatinous substances from the albumen, because gelatin is of a considerably inferior nourishing value than the pure albumen. This albuminous food, consisting of animal as well as vegetable albumen, contains at least $\frac{1}{3}$ animal albumen, as this is about the proportion in which the animal and the vegetable albumen are united in the general daily food. The first analysis of this food was published by König,² as follows:

Proteids	59.87 %
Water	8.89 %
Ash	1.24 %
Fat	0.20 %

Some other analyses, by various investigators, are about of the same tenor.

Lichtenfelt³ found as the average of 468 analyses:

Proteids	90.57 %
Water	8.41 %
Ash	0.87 %
Fat	0.15 %

Cellulose substance has been found to the amount of 0.01 to 0.03 %.

An elementary analysis has been made by Kunz,⁴ and was found as follows:

ANIMAL ORIGIN.	VEGETABLE ORIGIN.
C	51.498
H	7.862
S	0.788
N	16.028
O	23.184
Ash	0.64
C	50.232
H	7.167
S	0.788
N	16.028
O	23.004
Ash	2.74

These analyses represent the earlier products of the manufacturing process. In the meantime the methods of manufacturing have been improved, so that according to the more recently-made analyses an amount of 97 to 99 % of chemically-pure albumen has been found.* (Finkler, Plant.⁵)

In a paper on the valuation of foods, Dr. Lewith⁶ puts forth very interesting observations. Among a number of various foods he found that for the price of 1 florin, equal to about 50 cents, he could obtain the following number of calories out of the albumen (fat and carbohydrates respectively):

* More of recent date are two other albuminous food preparations—the one of entirely animal origin, and the other of entirely vegetable origin. For either it is claimed to possess merits, although I cannot speak from experience, as I experimented with the first only in small quantities, with the second not at all. Both are cheap, too, and easily resorbable, and would deserve a thorough trial.

FOODS.	ALBUMEN.	FAT.	CARBOHYDRATES.
Lard.....		12345	
Natural butter.....	ca20	8877	20.6
Oleomargarine.....	ca44	15443	45
Sugar, refined.....			10470
Beef.....	1152	1526	
Milk.....	1063	2475	1396
Milk, skimmed.....	2804	1103	4652
Eggs.....	791	1437	
Tropon.....	1200	(relatively expensive on account of import duties; refers to this country, too, where the duties amount to 25% <i>ad valorem</i> .)	
Potatoes.....	1476	619	34784
Bread.....	1390	325	3092

As a result of his researches he recommends on the one side oleomargarine as preferable to lard and dairy butter as a more valuable and more hygienic product, provided it comes from a good source, and because its production may be easier guarded in a sanitary sense than the other products, and on account of its being cheaper; for the same reasons he recommends Finkler's food as a clean and cheap and highly nourishing albuminous food. The indispensable 500 calories deriving from albumen are obtainable in—

Tropon.....	110 grams,*	3½ ounces.
Lentils.....	550 "	18½ "
Peas.....	650 "	21½ "
Beans.....	710 "	23½ "
Meat.....	720 "	24 "
Rice.....	1730 "	57½ "
Bread.....	2500 "	83½ "
Milk.....	3760 ccm.,	1 gallon.
Milk, skimmed.....	4450 "	1 gallon, 1 quart.
Potatoes.....	14100 grams,	30 lbs.
Eggs, 21 pieces.....	1100 "	36½ ounces.

This albuminous food can be resorbed at almost its entire amount—certainly to an extent of more than 90%; even as high as 95% (Strauss,⁷ Finkler). In Leyden's *Handbuch für Ernährungstherapie* we find a comparison by Klemperer as to the analysis of well-known food-preparations, whereby he makes a distinction between preparations with stimulating effect (Genussmittel), and such with nutritive effect. Among the former are:

	WATER	ALB., MEN.	SALTS	ASH.
Valentine meat juice ...	59.1	6.7	22.7	11.5
Liebig's beef-extract.....	17.72	20.5	38.29	22.74

Among the latter:

	WATER.	ALBUMEN.
Liebig's pepton.....	33.3	47.13
Somatose.....	9.2	80.00
Eucasin.....	8.0	90.00
Nutrose.....	8.0	90.00
Tropon.....		90.97

But we will immediately become aware of the great difference in the value of the various foods of this kind when we consider that the wholesale prices of 1 kg. of albumen amount in—

Tropon.....	\$1.00
Eucasin.....	2.80
Nutrose.....	5.00
Somatose.....	12.50
Valentine meat juice.....	41.50
Pepton Merck.....	5.25
Pepton Antweiler.....	10.00
Pepton Kemmerich.....	15.25

Finkler's nutritious albumen is on the market in different forms—the food plain, and combined with iron and iron-mangan and with sano (a 25% mixture of the

albumen and finest barley flour), as wafers, in combination with cocoa and chocolate.

The food in question had been used in the feeding of healthy as well as of sick people. Time would not allow me to give the growing literature on the use of this nutritious albumen. I shall only mention Professor Finkler,⁸ who fed a large number of consumptives and hysterics with a surprising result; thus it was possible in the case of a hysteric woman, who was in an excessive state of inanition, to increase her weight from 56½ pounds to 108 pounds, by administering first this pure albumen alone, and later on in mixture with other food. An excellent effect was exhibited in the nourishment of cases of phthisis, anemics, diseases of the alimentary apparatus and in acute diseases. Similar good results were found in cases of consumption by Dr. Knopf,⁹ of New York, and Dr. Martin,¹⁰ of St. Louis.

Dr. Pannwitz,¹¹ Regimental Surgeon in the German Army and Secretary-General of the Central Committee for Sanatoria for Consumptives, reports experiments with this food made on a lieutenant and 25 petty officers and privates. The experiment lasted for 3 days and nights. On an average they marched daily 30 km. (19 miles), and they camped during the night in the open air. The night rest was never more than 3 or 4 hours. The first night they camped at a temperature of 41° F., covered by tents around a fire of brushwood. The second night was warmer, but the rest lasted only 2 hours. In the third night they rested for only 3 hours in the woods without any campfire. Each man had three small parcels, each containing a day's ration of the wafers and the chocolate. Besides this, each man had 2 days' ration of a mixture of pea-soup or bean-soup in his bread pocket. The participants did not eat anything but this nutritious food except on the second evening some beer, and some coffee on the morning of the second and third day. On the evening of the third day they ate some bread and butter. The exclusive feeding with this proteid food was strictly enforced for 2½ days.

The method and partition of the food was as follows: Breakfast, coffee and the wafers. Until dinner, which was at 10 or 11 A.M., each participant could eat of the wafers or the chocolate; dinner consisted of the mixture with pea or bean-soup. Supper, the prepared chocolate cooked in water.

The nutrition was excellent, the digestion normal; in spite of the cold night temperature, no diarrhea; neither obstipation followed the change in the manner of life.

The weight of the 3 days' ration was 1,200 grams, while the weight of the common 3 days' ration amounts to 1,950 grams. This deficiency of weight may act as a relief to the soldiers, or they may make it up by carrying more cartridges.

Dr. Pannwitz made a second experiment for controlling the first. During the more extensive fall-maneuvers, 25 intelligent privates reported voluntarily for the experiment. They received as daily ration 100 grams of the wafers with sugar, 100 grams without sugar; 100 grams of the cocoa, and 100 grams of the peas mixture—equal to 400 grams; for 3 days, 1,200 grams. The food contained 130 grams albumen in the daily ration. The result was highly successful in spite of the most unfavorable circumstances as to weather, long marches, and irregular night-rest.

In connection with these experiments I like to mention two articles on the soldier's diet in the tropics, the one by Major and Surgeon W. O. Owen,¹² and the other

by Major and Surgeon J. R. Kean.¹⁵ These two writers stand to a certain degree diametrically opposite; Owen is for increased meat diet—Kean against it. Dr. Owen says, "It is not from choice that the laborer of the tropics lives on rice, bananas, etc., or the Irish cottier on potatoes, or the Eskimo on fat, but from necessity." At least to a great extent, for in the tropics vegetables and fruit are abundant and cheap whereas meat is expensive and hard to preserve, while in the Arctic regions the conditions are reversed. Owen reports that for several months he had charge of 300 convalescents and 50 nurses in the tropics, and found that they consumed all the beef, eggs, chickens, ducks, etc., that he could obtain for them, and they wanted more. At the end of the period they were in as good a condition as that of the inmates of any of the other hospitals in the neighborhood. His own personal experience was that so long as he tried to live on a vegetable diet in conformity to theory and tropical natives' custom, he was uncomfortable and despondent, and that when he resumed his full meat diet, his energy returned. Moreover, his native servants ate, with evident relish and benefit, all the meat that could be spared for them from the mess.

Dr. Kean, in his article "A Tropical Ration," says, "The digestion is weakened in hot climates and the liver is more inclined to torpidity. Fats are more difficult of digestion and absorption normally than carbohydrates, and when freely ingested in the tropics are extremely apt to split up in the stomach into butyric, caproic, lactic and other irritating acids, producing a condition of hyperacidity of the stomach-contents which the diminished secretion of the torpid liver is unable to neutralize and render alkaline."

This difficulty of the digestion of fat is well-known in the tropic and subtropic regions, but it refers only to the animal fat. As I mentioned elsewhere,* vegetable fat, as olive oil, cottonseed oil, may be used without any impairment of alimentary canal. Dr. Kean quotes Treille as saying, "In conclusion, the peoples indigenous to tropical countries are above all, but not exclusively, vegetarians. These habits do not proceed, it should be observed, from a backward civilization. For the great oriental lawgivers, who were true hygienists, took care from the most ancient times to forbid by religious laws the abuse of animal diet. This was because they had cogent reasons for doing so, and these were drawn from experience. They knew that too carnivorous a diet disposes in warm climates to certain diseases, and they had reason to fear that these would result in injury to the development of the race or nation. Hence, we find the prohibitions of the Mosaic and Mohammedan law and likewise of the Vedic, Brahmanic, and other religions of India where the Aryan race established so enduring a foothold."

As to the Mosaic laws, Treille must certainly be mistaken, for there is nothing in them to forbid a complete meat diet. It only forbids certain kinds of meat that have been known for many years to be the carrier of noxious agents to the human body. Furthermore, it forbids the use of the blood as the carrier of all that which is necessary to life on the one side and of the impurities to be eliminated on the other side; it forbids the eating of meat combined with milk or butter. In my previously quoted article I recounted the experience of a friend of mine who lived for many years in the Island of Java and in the Philippine Islands. He

told me that he never could understand the idea of the Mosaic dietetic laws till he came to the tropics, where the people very quickly learn to stop eating meat mixed with animal fat, such as butter or cream.†

I do not doubt that an addition of such a food, which can be preserved for an indefinite time without deterioration, would be accompanied by an excellent result in the feeding of the soldiers in the army as well as navy, and particularly in the tropics where fresh meat is very hard to keep for a longer time.

As to my experience with this albumen-food, I have used it for two years, and that in 27 cases‡ of healthy as well as of sick people, among others in 6 cases of anemia; 2 cases of pernicious anemia (1 case in the practice of a colleague); 1 case of acute vasomotor ataxia; 2 cases of achylia gastrica; 1 case of chronic mucous gastritis with large dilatation of the stomach; 1 case of neoplasma of the rectum; 1 case of renal calculi and cystitis; 2 cases of neurasthenia; 1 case of gastritis subacida with motor insufficiency; 2 cases of heart trouble, 1 complicated with chronic nephritis; 2 cases of diabetes mellitus, and others. One experiment I wish to mention. I decided to live on this nutritious albumen for one month, and I started on August 24; I ate for the following month no meat at all and replaced it by tropon food. I ate bread, butter, vegetables, potatoes, coffee, and I added at every meal from one teaspoonful to one tablespoonful of the preparation, mixing it with the food. I used the different kinds of the preparation; the best as to taste are undoubtedly the combination with the iron and iron mangan; then the wafers and sano-mixture, the latter particularly adapted to soups. At the end of the experiment, on September 23, I certainly felt in as good a condition as if I would have eaten meat, and since that time I have often used one or the other of these food preparations as a meal. This experiment proves, at least if nothing else, that this food can be injected in pretty large doses for any length of time without interfering in the least with the digestion and the well-being of the individuals. In cases of anemia the feeding of this nutritious albumen yielded excellent results;—better conditions of the blood as well as of the general health; loss of weight was never recorded even by feeding the plain albumen alone, except where anemia was accompanied by the so frequent state of obesity; in such cases I found flabbiness of the skin and muscles giving way to firmer skin and muscles,

* The Jewish dietetic laws are in fact Mosaic only to a certain extent; they are rather originating in the exponents of the biblical legislation, but undoubtedly they must have understood the hygienic laws to a degree that is marvelous. You might say they anticipated the whole bacteriology. Meat was not forbidden on account of a possible disagreement with the alimentary apparatus, but bad meat was forbidden, meat of animals which were not in an entirely sound condition. To begin with, only animals of apparently good health could be killed, and that only in such a manner that the blood could flow off as much as possible. The meat inspection was stricter than it was ever made by any other legislature. If after the slaughtering of the animal any kind of pathologic condition of the viscera was found, the meat was declared unclean in a religious sense and therefore not fit to be eaten. These lawgivers must have been pathologists, as they declare, for instance, that when the pleura is adherent to the lungs the meat of the whole animal is unfit for use unless the adhesions can be loosened without tearing; nodules in the lungs make the meat unfit; any ulceration on any of the viscera makes the meat unclean; kidneys as the carriers of the material of elimination were unclean. Even after the meat was declared fit to eat, it had to undergo a purifying process, it had to be rubbed in with salt and to be covered by it in a salt pan for a certain time and to be irrigated for another definite time; if meat was to be kept for a few days it had to be washed off, preferably in running water every 24 hours, ceremonies that show the wisdom of these ancient legislators. Another hygienic law of not less great foresight was, for instance, that no food ought to be touched with a hand not cleaned just for this purpose. Food standing over night was declared unclean. Metallic kitchen utensils were to be cleaned by exposure to fire, wooden utensils by rubbing with sandstone and water, such of glass by putting them under water and replacing the stale water by fresh water after a certain duration of hours unless it was a running water; all these laws, which are easily understood nowadays, when we know of the attacks of the armies of bacteria, were given as religious ceremonial laws in those olden times.

† A detailed report will be published later on.

* *Charlotte Medical Journal*, January, 1899.

with subsequent increase of flesh. The principal reason for this improvement was no doubt dependent on the fact that the body was nourished without being compelled to carry along a large ballast of water and undigestible remnants present more or less in all our foods.

The greatest amount of this albumen, about 3000 grams, was taken by the patient suffering from the acute vasomotor ataxia (S. Solis Cohen). In this case, I believe, it had a particularly good effect compared to the common proteid food, animal or vegetable, as it took away with the large bulk of indigestible remnants, a ready soil for putrefaction in the bowels, a fact which is not to be neglected in cases of this kind, where the etiology may be of the nature of autointoxication. Such autointoxication with symptoms especially of a nervous character cannot be denied after the elaborate researches of Bouchard, Albu and others.

In cases where the common meat diet is not advisable, as in uric-acid diathesis, this proteid food may be safely administered, since in the plain preparation the salts and nucleins have been removed; another form, to which the natural salts of nutrition have been added, has been put on the market, too, and used in many cases, especially in little children and where the food was given as exclusive food; this latter preparation has, on account of the presence of the various salts of nutrition, a more palatable taste than the plain preparation. In our times, where time is money, and in the times of the "Quick Lunch Restaurant," a more ideal and more nourishing food than these prepared wafers and this prepared chocolate cannot be thought of.

A short resumé of the nature and use of this nutritious albumen is as follows:

1. This food is a powder of almost chemically pure albumen of animal and vegetable origin in the average proportion in which the daily food is usually mixed.

2. This powder is of slightly brownish color, odorless and tasteless.

3. It is sterile, and can be kept for any length of time under any climate without deterioration.

4. The plain preparation is not soluble in water, but is readily accessible to the secretory juices of the alimentary apparatus. The iron mixture is soluble.

5. It is resorbable to an extent of more than 90% of its weight taken into the body.

6. It can be eaten as food by itself, or readily be added and mixed to any other food without changing taste or flavor of the food.

7. This nutritious albuminous food, because of its high degree of resorbability, is an exceedingly cheap proteid food for the sick as well as for the healthy person. Particularly it must become an ideal albuminous nourishment for the soldier in army and navy, and for the traveler in the far North as well as under the tropic sun.

8. This food, on account of its small bulk and absolute digestibility, yields excellent results in all cases of malnutrition of the insane, the anemics, the consumptives, the sufferers from gastric and intestinal diseases, and the acute infections, and in the subsequent convalescence; furthermore, in all cases of disturbed metabolism, such as diabetes mellitus and gout.

9. Because of its insolubility in water it does not lose any of its good qualities; on the contrary, it is preferable to soluble and predigested foods in the greatest number of cases where an artificially prepared food is necessary.

10. This food, like several other artificially manufactured foods, including oleomargarine [sold as such] will and must become the foods of future periods, especially when the number of the population shall have increased to such a degree that all available space must be given to the people, and the factories, where all the necessities of life have to be manufactured; these preparations must become the food wherever the success of an undertaking is dependent upon the maintenance of the enterprising parties by the least possible ballast and the best possible nourishment.

THE FUNCTION AND DISTRIBUTION OF COMBINED HYDROCHLORIC ACID IN PROTEOLYTIC DIGESTION.*

By A. E. AUSTIN, M.D.,
of Boston.

By the term combined hydrochloric acid is meant, of course, that portion which is united with albumin or albumose, in distinction from the free, and that portion which is more firmly combined with the alkaline bases. This latter is a true chemical combination, while we shall be able to show in the experiments which follow that the loosely combined may be regarded as simply an adherence of the acid to the albumin which serves the purpose of base. This combination in fact is so unstable that it can be disassociated by alcohol, heat, and all bases which have a greater affinity for chlorin than the albumin itself. Thus, in the Sjöquist test, barium easily combines with the chlorin which is taken from the albumin, forming barium chlorid, while in Leo's test calcium serves the same purpose. This combination of albumin and chlorin seems absolutely necessary for digestion by pepsin, since the latter apparently does not digest albumin, but acid albumin or better hydrochlorid of albumin, the formation which seems always an essential preliminary to the further disintegration of the albumin molecule.

For the accomplishment of this combination it is useless to talk of percentages of hydrochloric acid and water, as it seems to make but little difference, as regards the ratio of hydrochloric acid and water, provided that there is enough hydrochloric acid to saturate the albumin. What is of vastly greater importance is the ratio of the albumin to water, since in order to affect this combination, the albumin must always be in solution. The problem of the action of pepsin is a distinct and different one, for we know that we may readily provide such a concentration of hydrochloric acid that it has an inhibitory effect upon the activity of pepsin. If digestion by pepsin is hydration, then we can readily conceive why excessive dilution of the albumin solution upon which it acts is so necessary. Nor is hydrochloric acid the only one which can form acid albumin upon which pepsin may act. Lactic,

* From the Laboratory of Physiological Chemistry, Tufts College, Boston.

acetic, and other acids may perform the same function. As to the conditions which favor the production of acid albumin, we are not wholly clear; the first essential, of course, is enough hydrochloric acid. Simon in his "Clinical Diagnosis" gives a list of albuminous substances, and the amounts of hydrochloric acid which they can respectively combine, but nothing is said in this of other modifying conditions. Temperature apparently aids this combination, as does also persistent and frequent shaking. Further, hydrochloric acid does not attack albumin well, when mixed or surrounded by fat. It appeared a matter of sufficient interest to investigate at length the conditions which modify and affect this union between hydrochloric acid and albumin. One of the first ones considered was that of concentration.

EFFECT OF CONCENTRATION.

In order to demonstrate this, five solutions were prepared, each containing respectively 1000, 500, 250, 200, and 100 cc. of water, with 2.5, 1.25, .625, .5 and .25 gm. of HCl. To each of these was now added 10 gm. of dried egg albumin, and all were digested 24 hours at 38° F.

The free hydrochloric acid was now determined by dimethylamidoazobenzol and tenth normal NaOH, and deducted from total HCl used, whereupon it was found that each gram of albumin in the first solution had combined 21 mg. HCl, of the second 23 mg., of the third 27 mg., fourth 25 mg., and of the fifth 25 mg. It is of interest here to note that while the percentage of hydrochloric acid always remained the same, and the total amount of HCl steadily diminished, yet with decreasing amounts of water, in which the albumin was dissolved, the latter was able to grasp and hold more hydrochloric acid.

This process was then repeated, but in a somewhat different manner. An insufficient amount of hydrochloric acid for saturation as determined by the previous experiments was added, and after the digestion was completed, tenth normal HCl was added in presence of demethyl until free acid was present, then the total HCl obtained, four solutions were prepared which contained 100 cc. of water, 10 grams of egg albumin, and respectively 250, 270, 275, and 330 mg. of hydrochloric acid. After adding to each an amount necessary to show the presence of free acid, it was found that one gram of albumin had combined respectively with 28, 27.6, 33, and 33 mg. HCl. In other words, while not enough was present to show free acid, with gradually increasing percentages of HCl, the albumin had taken up more of this by subsequent addition than in the previous experiment. In fact the gradual addition of hydrochloric acid will cause the albumin to absorb more than though it is placed in contact with more than its usual quantity of combination. As the last two experiments came out alike, no further effort was made to increase the concentration of the hydrochloric acid.

This latter experiment is not fully satisfactory, because the eye trained to observe the change with dimethyl, from red to yellow finds great difficulty in noting the reverse change of yellow to red, and the exact point at which all of the albumin is saturated is difficult to determine.

Here we have a varying concentration of HCl, from 2.5 to 3.3 per thousand.

EFFICACY OF ACID ALBUMIN IN DIGESTION.

It was now considered advisable to determine whether acid albumin had lost its efficacy in the further digestion of native albumin with the acid of pepsin. Starting from our previous experience, that each gram of albumin would hold about 30 mg. of HCl in combination, 50 grams egg albumin were dissolved in 500 cc. water, 1.5 cc. HCl added, and the whole placed in a brood-oven for 24 hours. At the end of this period it was removed, filtered, evaporated, and dried at a low temperature. It is necessary to add that no free acid could be detected by dimethyl. This preparation kept perfectly well, but was redissolved with difficulty, in fact not all of it could be dissolved even upon warming. The addition of a drop or two of tenth normal HCl, caused reddening with dimethyl, showing that it was fully saturated with HCl. With this preparation several digestions were preformed in the following manner: Two similar solutions were prepared, one containing .1 gm. acid albumin, no native albumin, .1 gm. pepsin, and 100 cc. of water. The other was prepared in the same way, but .5 gm. of native albumin was added. After 24 hours the coagulable and acid albumin were removed, the albumose peptone in each was determined by centrifugation, and also in some cases by the comparative amounts of nitrogen. The first combination contained .16% albumose peptone, while the second with the native albumin contained .26% albumose peptone. In the second series 2 gm. acid albumin were used in the first, while the second contained the same plus .5 gm. native albumin. The first of these series had .23% albumose peptone, or 37 mg. nitrogen, while the second showed .33% albumose peptone, or 53 mg. nitrogen. Of the third series No. 1 had 1 gm. acid albumin, while No. 2 had the same plus 1 gm. native albumin. The result of this digestion was .26% albumose peptone or 37.8 mg. nitrogen in No. 1, and .43% albumose peptone or 42 mg. nitrogen in No. 2. Fourth and last series had 1 gm. acid albumin in No. 1, and the same with .5 gm. native albumin in the other. The result of this digestion was .9% albumose peptone, or 109.2 mg. nitrogen, and 1.06% albumose peptone, or 120.0 mg. nitrogen in the other. In every case a marked increase in the amount of albumose peptone, and consequently of nitrogen, was discovered in those digestions to which native albumin had been added. As the theory of digestion presupposes that the native albumin must have been converted to acid albumin, it must have obtained its hydrochloric acid from the acid albumin. Riegel makes the statement that free HCl can do still further digestive work, while the combined HCl has already done such work. It would seem that acid albumin or acid peptone before absorption could give up a portion of its HCl, which could again serve its purpose of converting native to acid albumin. In no other way can we account for the fact that stomach-contents which show no trace of free HCl, have still quite a marked digestive power when brought in contact with fibrin or egg albumin. This has been the experience of the author in several cases where routine examinations for pepsin have been made in stomach contents. This condition is distinctly different from those where alkalies in the form of bile, or succus entericus unite with the HCl; there, as is well known, all digestion ceases. It is also noticeable that when 2 gm. acid albumin instead of 1 were used, the increase in digestive products was much greater. For instance

37.5 mg. nitrogen to 53.2 mg. nitrogen in place of 109 mg. to 120 mg. nitrogen, but the total amount of nitrogen in the form of albumose peptone was much greater in the latter case. An amount of 2 gm. of acid albumin when digested produces less nitrogen than 1 gm. of acid, and 1 gm. of native albumin, by nearly 5 mg. This is another proof that the native albumin must take up HCl from the acid albumin.

EFFECT OF DIALYSIS.

It is a well-known fact that the major part of the digestive products pass through a dialysing membrane; at least primary and secondary albumoses as well as peptones do this, and, while it is not generally stated, my experience showed that acid albumin would also pass through an animal parchment. With the expectation that free acid with digestive products would pass through such a membrane to a large extent, leaving coagulable albumin and acid albumin behind, a series of digestions was prepared in the inner receptacle, while the outer contained only distilled water. This then remained in the dialyser 24 hours in the brood-oven. At the end of that time free hydrochloric acid was determined both in the inner and outer fluids, after being measured, by N-10 NaOH and dimethyl while the total free and combined was determined by the Sjöquist method. Efforts were made to separate the free acids by distillation, and also to separate the combined acid by precipitating the albumose peptone, with which it was combined by alcohol. Both attempts were utterly futile. Other difficulties were also met with. It was found that there was no surety that all the albumose peptone would pass through the membrane, even when dialysed against running water, and furthermore acid albumin was repeatedly found in the outer fluid. In spite of these difficulties which impaired the value of the work, some of the factors are worthy of mention. In the first effort 5 gm. of dried egg albumin, .2 gm. pepsin, .5 gm. HCl and 250 cc. water were placed in the inner receptacle, while in the outer there were 550 cc. water. At the end of 24 hours the contents were removed from both vessels, carefully evaporated to 100 cc. at a temperature of 40°, and 10 cc. of each taken for the determination of free and total HCl, from which the combined was calculated. In the inner were found 174 mg. free HCl, 103 mg. combined and 140 mg. nitrogen; in the outer there were 183 mg. free HCl, 28 mg. combined and 65 mg. nitrogen, or a total of 488 mg. HCl, and 205 mg. nitrogen. In digestion No. 2, 10 gm. albumin, .5 gm. pepsin, .4 gm. HCl, and water as before. After the digestion was completed, the inner fluid had 73 mg. free HCl, 46 mg. combined, and 308 mg. nitrogen, while the outer had 94 mg. free, 16 mg. combined HCl and 210 mg. nitrogen, or a total 229 mg. HCl, and 518 mg. nitrogen. The enormous loss of HCl here experienced, can only be accounted for by the loss in evaporation from the dialyser. Digestion No. 3 had 5 gm. albumin, .2 gm. pepsin, .2 gm. HCl, and after digestion the inner had no free HCl but 100.2 mg. combined HCl, while the outer had no free HCl and 40.8 mg. combined HCl, making a total of 141 mg. No. 4 had all the ingredients of the previous digestion, but only 150 mg. HCl; at the close of the digestion the inner had no free HCl, but 55.1 mg. combined HCl, while the outer had no free HCl, but 25.2 mg. combined HCl, or a total of 80.3 mg. In the last two digestions no effort was made to concentrate the solution for fear of loss of HCl, and

calculation was made up in aliquot parts of the original solutions. Among the points which were here noted was this: that as long as the acid was in excess of the combining power of the albumin, it passed through the membrane freely, but not until the demands of the albumin were satisfied. As soon, however, as the HCl approached the saturating point of the albumin, no free HCl was found in the external fluid. It appeared that when the digestive products were fully or even partially removed by dialysis, a certain amount of albumin would take up no more HCl than when simply combined. As, for instance, in No. 3, 28.2 mg. per gram of albumin instead of 30 mg., the largest amount which could be made to combine in our first experience. Another explanation of this fact, which is more fully brought out in later experiments, is that the albumoses and peptones will take up much more chlorin in the proportion to the amount of nitrogen contained, than the simple albumin. This seems opposed to pepsin, by which more albumin can be digested, if the digestive products be removed by dialysis. A part of the loss of HCl as compared with the original amounts used can perhaps be attributed to the difficulty of filtering barium sulfate in the Sjöquist test, which is only retained with difficulty by the finest filter paper. These experiments lead to no definite results as to the distribution of hydrochloric acid, because no complete separation of the digestive product could be made.*

SEPARATION BY METALLIC SALTS.

This effort was made in order to demonstrate, if possible, the greater combining power of albumose and peptone for chlorin, as well as to learn, if possible, how the chlorin was distributed with reference to the different digestive products in a completed digestion. It was assumed naturally that each of the digestive products when separated from the solution carried with it the chlorin with which it was combined. These digestions were prepared, and after 24 or more hours the coagulable albumin was removed by boiling with a drop or two of acetic acid, the acid albumin by sodium carbonate, the primary albumose by the addition of copper acetate in solid form until equal to 2% of the total solution. The precipitate was washed by a saturated solution of copper acetate, while the secondary albumose was precipitated by adding 2 cc. of 25% sulfuric acid to each 100 cc. of fluid, and then zinc sulfate added to this until a saturated solution was obtained while warm, as evidenced by deposition of some of the zinc sulfate when cool. This precipitate was removed, washed with saturated sulfate solution, and the filtrate, containing peptone and certain amido acids, was preserved. The acid albumin was suspended in water, the copper removed from the albumose, dissolved in water by H₂S. The secondary albumose was redissolved and the peptone in solution was freed from zinc by exact neutralization, and then each solution was divided into 2 equal parts, the one half was evaporated with 5 grams of saltpeter mixture (3 parts nitrate of potash and 1 part of sodium carbonate) and burned, and the other half reduced in volume, and its nitrogen was determined by the Kjeldahl method. By this method the portions which were burned were freed from organic matter and the chlorin, after neutralization with HNO₂, could be determined by a standard solution of silver

* After completing this work to this point, my attention was called to the fact that Gillespie had done similar work, published in *Journal of Anatomy and Physiology*, vol. xxvii, p. 201, to whom credit for priority is due, but not for any suggestion to me.

nitrate. The 5 grams of saltpeter mixture contained quite uniformly as an impurity, 3 mg. of chlorin, which were deducted from the total found in each case. The amount of hydrochloric acid used in each digestion was 600 mg. of dilute, which, as determined by the standard silver solution, contained 164 mg. of chlorin. The egg albumin used was found free from chlorin, but contained 465.5 mg. nitrogen per 5 gm. albumin. Digestion No. 1 consisted of 5 gm. albumin, 600 mg. HCl dilute, 200 mg. pepsin, and 200 cc. of water. Period of digestion was 25.5 hours. There were found combined with the acid albumin 20.4 mg. chlorin, with the primary albumose 24 mg. chlorin, with the secondary albumose 18 mg. chlorin, and with the peptone 100.8 mg., or a total of 163.2 mg. The respective amounts of nitrogen in these separate products were 16.2, 12.3, 5.6, and 12.6 mg. nitrogen, or a total of 46.7 mg. No. 2 was similar to the former except that 150 cc. of water was used. Period of digestion, 24 hours. There were combined as acid albumin 24 mg. with primary albumose 15.6 mg., with secondary albumose 40.8 mg., and with peptone 81 mg. chlorin, making a total of 162 mg. The corresponding amounts of nitrogen were 22.9, 1.9, 5.6, and 21 mg. nitrogen, making a total of 51.4. No. 3 same as former, but

thing is that the acid albumin, so called, appears to have no regular formula for its composition. We find in this form 16.2 mg. nitrogen combined in one instance with 20.4 mg. chlorin, and in another instance 6.1 mg. nitrogen in the form of acid albumin combined with 18 mg. chlorin. This amount of chlorin is so very much larger than we can cause to unite with native albumin without the aid of pepsin, that this must represent a rest or residue of the albumin molecules from which the more easily split-off portion undergoes further change into albumose peptone, which contains much stronger basic properties. This is found pretty generally throughout. For instance, 12.3 and 11.2 mg. nitrogen as primary albumose combined with 24 mg. of chlorin. In one of these the nitrogen in the albumose was found to be about 12%, so that we find an equivalent of 102.5 and 93.3 mg. of primary albumose uniting with this amount of chlorin, making vastly more than can be made to combine when these two are brought together apart from digestion. For instance, Otto Cohnheim could only make one gram of protoalbumose in 2.5% solution take up 43 mg. of HCl, while heteroalbumose takes up 81 gm. to the gram, and in a 1.25% solution protoalbumose took up 35 mg. HCl, and heteroalbumose took up 45 mg. to the gram. We can therefore

100 cc. of water was used. Period of digestion, 96 hours. There were found combined as acid albumin 18 mg., as primary albumose, 39 mg., as secondary albumose 10 mg., and as peptone 114 mg. chlorin, or a total of 181 mg. Corresponding amounts of nitrogen were 6.1, 3.6, 1.6, 39.2 mg., or a total of 0.5 mg. No. 4 same as former, but with 50 cc. water, acid albumin had 10.2 mg., primary albumose 24.6 mg., secondary albumose 18.6 mg., and peptone 113.4 mg. chlorin, or a total of 166.8 mg. Corresponding to each of these were respectively 10 mg., 11.2 mg., 7.5 mg., 39.2 mg. nitrogen, or a total of 67.9 mg. In none of these was free acid ever discovered by dimethyl. These factors are here shown in tabular form.

The most noticeable thing about these digestions is the inefficient nature of the digestive process. There was by actual estimation 455.5 mg. nitrogen in the original albumin, but only from 46.4 to 67.9 mg. could be found in the sum of the digestive products. This was probably due to the great ratio of albumin to water in the solution. The inhibitory action of albumose peptone upon the farther digestion by pepsin was apparently increased by their greater concentration. The major part of the nitrogen was, of course, removed in the coagulable albumin, which was not taken into account because not a part of the digestive products, containing no chlorin in combination. Another noticeable

conclude that they have vastly stronger basic properties than the native albumin, and in general we may say that each stage of the digestive process enabled the nitrogenous substance to increase its chlorin-containing powers until the acme is reached in the peptone. The relative amounts of the different albumoses in the various digestions vary so greatly that it is hard to draw any conclusions as to distribution of the nitrogen. In the first two the major part of the nitrogen is found in the two extremes, acid albumin and peptone, but in the latter the nitrogen gravitates more toward the peptone end of the line. E. Zuntz (*Zeitschr. f. physiologische Chemie*, vol. xxviii, p. 141) finds in a digestion 1.12% of the total nitrogen as primary albumose, 11.7% as secondary albumose, and 87.18% of the total in other nitrogen-containing products. He used serum albumin and much larger quantities of water, 275 cc. to 5 grams. My most favorable results only approximated this after 96 hours digestion with still 1.7% as acid albumin, and 77.6% as other nitrogen-containing products. Zuntz does not regard all of the remainder, nonprecipitable by zinc sulfate, as peptone, for an amount of nitrogen varying at different periods of digestion from 34.8 to 62.47% of this is not precipitable by phosphomolybic acid and sulfuric acid. This substance was probably of the nature of amido acids, for they could be precipitated by tannic acid and other alkaloidal reagents.

The Philadelphia Medical Journal

A Weekly Journal Owned and Published by The Philadelphia Medical Publishing Company and Conducted Exclusively in the Interests of the Medical Profession

JAMES HENDRIE LLOYD, A.M., M.D., *Editor-in-Chief*

JULIUS L. SALINGER, M.D., *Associate Editor*

Assistant Editors

JOSEPH SAILER, M.D.

Recent Phases of Medical Legislation.—State Legislatures and Governors in various parts of the United States are having opportunities at present to display the degree of natural intelligence with which they are endowed with reference to the greater questions of public health. In New York at the time of the present writing we are glad to know that there is a prospect of a passage of the so-called Bell bill by the Legislature. This bill will compel all such so-called practitioners of medicine as osteopaths and Christian Scientists to submit to the same regulations and take the same examinations as are required by the graduates of recognized medical schools. The justice of this measure is so obvious as to need no comment. It is in our opinion the most practicable, if not the only practicable, way to suppress these unqualified practitioners. It obviates the necessity of any criticisms of their various tenets and beliefs. It merely requires of them a demonstration of their fitness to practise medicine, and it effectually suppresses them if they are found not to be competent.

In some of the Western States, we are sorry to see that this subject of State control of the practice of medicine is not receiving the intelligent consideration which it demands. Some Governors of States as well as legislators show with reference to this question that they have little appreciation of the duties imposed upon them as guardians of the public welfare. It is very evident, as we said in these columns in discussing Dr. Wyman's recent address before the Pan-American Medical Congress, that the public and the servants of the public in this country require a more careful education in the subjects of hygiene and medicine. For crass ignorance and perversion of judgment, the Governor of the State of Washington (Rogers, by name) has shown that he is preeminent. He has just vetoed an act passed by the Legislature to control medical practice in that State, because it ruled out the osteopaths. In addition to this pernicious exercise of his prerogative he has indulged in a senseless tirade against the medical profession. He professes to believe that the osteopaths are teaching educated physicians the way to cure diseases without the use of deleterious drugs, and he claims that the contents of the drug stores are perhaps more dangerous to the future well-being of the human race than are the saloons. To criticise such a public official is useless; it is sufficient to quote him.

In California the Legislature has persisted in putting Christian Scientists on an equality with graduates of the recognized schools of medicine. Its motives for so doing seem to have been that these sectarians are numerous and a good class of people; a reason which the *Sacramento Bee* (quoted by the *Journal of the American Medical Association*) says would have been as pertinent if applied to the inmates of the various lunatic asylums of the country. In connection with this class of legislation the recent eruption of Mark Twain is perhaps worthy of a passing notice. He has appeared before a committee of the New York Legislature in favor of legalizing osteopathy. Fortunately Mark Twain's entire reputation is that of a so-called humorist, but his recent championing of osteopathy is as devoid of judgment and knowledge as some of his more recent productions are lacking, in the estimation of men of good taste, in the essential qualities of humor.

The Liverpool Tropical School on Yellow Fever.

—In the *British Medical Journal* of February 23, 1901, appears the abstract of the interim report of the Yellow Fever Expedition of the Liverpool School of Tropical Medicine. The investigations were conducted by Dr. Herbert E. Durham and Walter Myers, M.B. They were, unfortunately, interrupted by both of these observers suffering from attacks of the disease. Most regrettably, Mr. Myers' case proved fatal, and it was deemed wise to publish the incomplete report. This furnishes us with a valuable contribution on the subject of the etiology of yellow fever. The investigators have found in all fatal cases of the disease, after thorough search, a small bacillus somewhat resembling that of influenza. They have been able, upon examining the organs after death, to discover this bacillus in the kidneys and spleen, and in the mesenteric, portal, axillary and lymphatic glands. Apparently the same bacillus is often found in extraordinary preponderance over the other microorganisms in the lower intestine. Preparations of the organs fail usually to show the presence of any other bacteria. They believe that this bacillus has been observed by Dr. Sternberg and two others, and they attribute the fact that no etiological importance was attached to the bacillus, to the employment of insufficiently stringent staining technique, owing to which it was not found constantly. They have not been able to obtain pure cultures of the organism in

either aerobic or anaerobic culture tubes. They have, however, obtained pure cultures by placing whole mesenteric glands cut out by means of the thermocautery in broth, under strict hydrogen atmosphere. Most careful search was made for parasites of the nature of protozoa, but none were found. They conclude, consequently, that yellow fever is not due to this class of parasites. Durham and Myers were not familiar with the concluding report of the American Commission, but they were far from being convinced of the commission's logic in the deductions of its preliminary report.

The concluding Report of the American Commission read recently before the Havana Pan-American Congress (and which we have commented upon editorially) has received wide support, and would probably satisfy certain objections which Durham and Myers found in the preliminary work. These authors conclude by stating that there is much etiological importance to be attached to the fine, small bacillus which they describe, and they suggest that the acquisition of a new intestinal bacterium would explain the immunity of the "acclimatized." They have examined the blood and organs of fourteen fatal cases of yellow fever, with painstaking care, and the report of their studies is entitled to respect. They may be criticized, however, for a lack of thoroughness in their deductions. No experiments seem to have been performed upon animals and the etiological relation between this fine, small bacillus and yellow fever cannot be considered by any means as definitely established. At the present writing, while we must suspend judgment, it would appear that the views of the American Commission are far more conclusive than the abstract quoted, yet it is but fair for us to await the promised completion of the Report of the Expedition of the Liverpool School of Tropical Medicine before attempting a judgment of its work.

The Influence of Sterilized Air Upon Animal Life.

"Therefore as a result of the experiments made by me in 1893 and 1894, and during the present year, upon the influence of sterilized air upon animals, I maintain that, besides the oxygen of the air, certain microorganisms of the air are also necessary to maintain life and the normal metabolism in the tissues. These microorganisms enter the blood during the interchange of gases and are devoured by the leukocytes (hence they are not found in normal blood), then, after they have been digested by them, they give rise to the formation of ferments without which the normal process of oxygenation in the organs rapidly diminishes, and is replaced by the formation and accumulation of a large quantity of incomplete intermediary products of tissue metamorphosis, that is, by leukomaines, which cause the death of the animal."

This is, to say the least, a startling assertion. Kijanitzin (*Virchow's Archiv*, 162, p. 515), who has done

much work with sterilized air, has performed a number of experiments by placing sterile newly born and other animals in sterile vessels, and supplying them with a sterile atmosphere. Under these conditions the animals emaciate, as a result of a marked increase in the nitrogenous excretion compared with the nitrogenous intake, and a large proportion of them die in five days, or less. It does not appear possible that this is due to the formation of any poisonous element in the air, as a result of the intense heat to which it has been subjected; and CO was not present in the blood of the animals after they died. Therefore it seems reasonable to suppose that the mere fact that the air was sterile, that is, contained no microorganisms, must be the true explanation.

The author supports his doctrine by the following arguments. First, that most of the normal ferments of the blood are found in the leukocytes. Second, in certain pathological states certain of the pathogenic microbes are digested by the leukocytes and give rise to the formation of substances that possess the characters of ferments. Third, the non-pathogenic microbes, instead of being absolutely neutral, exert, under certain circumstances, considerable influence upon the tissue, especially upon the leukocytes. Fourth, the fact that the animals subjected to the experiment died not only in the apparatus, but frequently from ten minutes to an hour and a half after their removal from it, when they had been supplied with ample nourishment and everything to enable them to recover, is an indication that some profound alteration in their economy had taken place.

In order to determine what this alteration was he made careful *estimation* of the nitrogenous metabolism, and found that the proportion of the total nitrogen in the urine to the nitrogen in the urea, which, in normal animals is about 100 to 90, in the animals subjected to this experiment was altered to 100 to 55, and even less, as a result of the enormous increase in the proportion of leukomaines.

The interesting feature about this paper is the light it throws upon the moot question of the advantage of bacteria in the economy of the higher animals. It has been supposed, in fact it has been accepted, that the bacteria of the intestine are concerned in the digestion or at least in the disintegration of cellulose, but, aside from this, no actual benefit derived from their action has ever been definitely proven, excepting of course those very indirect benefits that result from the formation of antitoxins.

If Kijanitzin is correct we must modify our views, or rather agree to believe that the ferments of the blood, which by the way are not as well known as they should be, but whose functions are undoubtedly of the greatest importance, are produced largely, if not exclusively, as a result of the conversion of the bodies of bacteria obtained from the atmosphere by the action of leukocytes.

If one should allow one's imagination to run riot it

might dream of the treatment of various dyscrasias by saturating the air in which the patient should be placed, with certain forms of bacteria whose bodies should supply the missing ferments.

The Registration of Tuberculosis.—Amid the controversy which this subject is bound to excite—a few tones of which can already be distinguished in the columns of the JOURNAL—it were well for every one to pause long enough to endeavor to gain a clear view of what after all is the vital question. This, it seems to us, is the old and ever recurring question, in hygiene as in every other sociological science, of what is the greatest good to all. It is not a question that is to be argued on purely sentimental grounds, or even exclusively on the ground of the sensitiveness and welfare of the individual, but of the one imperative consideration of the public welfare. Is this infectious disease controllable, and, if so, how is it to be best controlled? Is it to be allowed to go about unrestrained, slaying yearly its thousands and tens of thousands, lest, perchance, an effort to control it should wound the feelings or the scruples of a minority? In other words, is the majority to be exposed to a constantly active risk rather than that the invalided minority should be in some remote way put to inconvenience or exposure? The question needs but to be put in order to answer itself. The principle involved is already acted on in the case of every contagious disease, and human society for its own good can and will be satisfied with nothing less than protection. It is absolutely needless to dwell upon the so-called hardships of the law. They are greatly exaggerated, and such as they are they can be practically ameliorated in many ways.

The force of all arguments, *pro* and *con*, bears eventually upon the question simply of public welfare. Practically the problem resolves itself into this: If this or any disease is to be subject to State control, there must be a way to allow the State to gain knowledge of its whereabouts, and in the case of tuberculosis there seems no practicable way but by means of registration.

The New Medical Bulletin of the University of Pennsylvania.—The medical faculty and graduates of the University of Pennsylvania are to be congratulated on the appearance of the new medical periodical which comes out this month under the title of *The University of Pennsylvania Medical Bulletin*. This first number is very attractive in appearance and in its table of contents. Dr. Francis R. Packard contributes the first of a series of papers on medical men prominent in civil and military affairs in revolutionary times. This paper has all the interest which attaches to Dr. Packard's literary and historical work. Dr. J. William White publishes a valuable paper on the Treatment of Trifacial Neuralgia, with the report of a case of evulsion of the second and third divisions and of the Gasserian

ganglion. At the end of 11 months the patient remained free from pain. Dr. Charles H. Frazier and Dr. Montgomery H. Bigs contribute an important paper on the Value of the Tuberculin Test. Their conclusions are given at length, and should be read in the original. Dr. John H. Jopson contributes a digest of recent literature on Perforation of the Intestine in Typhoid Fever. The number concludes with copious alumni notes, which will be of great interest to the graduates of the University.

This new *Bulletin* is to be published once a month, and is to take the place of the former *University Medical Magazine*. It is to represent exclusively the University, not the work of those only who are actively connected with the faculty, but of the whole alumni body. It is to be a purely scientific periodical, without advertisements, and promises under the able editorial care of Dr. Frazier to be in every way a worthy exponent of the oldest medical school in the United States.

The Assault on the Kaiser.—If the earlier reports are accurate the recent assault on the German Emperor was made by an epileptic, and the case has therefore more medico-legal than political interest. It is said that the assailant, after throwing a piece of iron at his Majesty and wounding him slightly on the cheek, had several fits, and that he was found, on investigation, to be the victim of chronic epilepsy. It is premature perhaps to comment on the case, but it may not be inappropriate to express the hope that the assault may be found to have been the act of an irresponsible man. Epilepsy, as is well known, predisposes its victims to just such impulsive and maniacal outbursts as this act of Weiland seems to have been. Such patients sometimes act in an automatic or seemingly purposive manner, when in fact they are quite unconscious of the nature of their acts, and have no memory of them. This is especially true of the post-epileptic maniac, who may continue to display a true psychosis for hours or even days after a convulsion. It is also true of the victim of those curious substitutional attacks which replace the fit itself, and, as the name implies, substitute for it a delirium in which delusions and wild impulses have full sway. In the *épilepsie larvée*, or concealed epilepsy, of Morel, the motor crisis may never or rarely occur, but a periodical or occasional furore may be the sole symptom. This is one of the most involved of all the vexed questions in medical jurisprudence, and it is to be hoped that this assault on the Kaiser may have at least the one good effect of subjecting the whole question to renewed investigation and profitable criticism.

The Treatment of Cancer.—Professor L. Lewshin remarks that during the last 33 years of his surgical practice no material improvement has taken place in the treatment of cancer. The percentage of complete

recoveries following surgical intervention, as attested by European surgeons, is still very small even in operable carcinomas. On the other hand, the statistics of Massey, Heyman, Czerny and others establish beyond doubt the alarming fact that cancer, especially of the digestive organs, is on a progressive increase. In Moscow there occurred in 1880 411 deaths from cancer, while in 1896 the number of deaths from this disease reached 892, almost doubled. It is to be regretted that the author does not state the extent of the increase in population during the same period, but it may be assumed that he has taken this into account in making his deductions. To the hundreds who die there are thousands who drag out a miserable existence, a burden to themselves and their families and a ready prey to the quack. These unfortunate sufferers should be taken care of. Moreover, the rapid increase of an incurable and fatal malady renders of paramount importance the study of the disease in all its phases. Both the humanitarian and scientific purposes could only be accomplished by the establishment of proper sanatoria. Such an one is being established in Moscow through the efforts of Professor Lewshin, who has already received private contributions to the amount of 300,000 roubles (about \$150,000). The city council of Moscow pledged itself to pay for the maintenance of 50 patients for 10 years, while the medical faculty of the Moscow University has taken the sanitarium under its protection as an addition to the university clinics.

Plague News.—According to the Marine Hospital *Health Reports*, India is still the great theater of plague. In some districts of the vast Hindu empire cases were being reported in the early part of the winter by the hundreds, and even thousands. In the Patna city and district, in Bengal, 5,506 cases occurred during November, December, and January, and of this number 4,810 cases were fatal. A glance at the list of infected regions in India, with the tabulated figures of cases and deaths, showing as usual a very high mortality, does not inspire the reader with the belief that the disease is under any sort of control in that country, or with the hope that even with serum-therapy and prophylaxis its spread will be checked before the onset of summer. India is at present the most active focus of plague on the face of the earth, and her condition is a grave menace to mankind in general. If the disease does not spread from her territory to other countries, and become as unmanageable in them as it is in her, it will be almost miraculous. In Japan, China, and Formosa there is very little plague that is being reported. In Japan especially the disease seems to have been fought with great intelligence and success. In Brazil there is still some of it lurking in Rio de Janeiro, and the mortality is high, but the number of cases is not great. The reports contain no mention of plague in San Francisco, so we might hopefully and charitably suppose there is none

there, if we did not believe that the truth has been suppressed—a state of things for which the U. S. Marine-Hospital service is not responsible. It is unfortunate that that city has aroused a suspicion that the disease has been concealed by the local authorities. A delegation of San Francisco citizens in Washington have just given out a remarkable statement that no case of infectious bubo-pneumonic plague has been found in California, but that all the cases have been of a “non-contagious character.” This is a truly alarming statement, for it acknowledges the presence of plague while it attempts to mitigate the fact by claiming that the disease is “non-contagious”—a self-evident contradiction that goes far to discredit either the knowledge or sincerity of those who made it—or both. In Cape Town, South Africa, 15 new cases were reported on the 11th inst. In the Philippine Islands there were but 2 cases. There is plague in Russia (more than 100 cases of it) and in Smyrna in Turkey. From this latter port a steamer arrived at Bristol, Eng., on January 21st. laden with barley, with a clean bill of health. The following day dead rats were found in the hold, and in their bodies were found the plague bacilli. Extra precautions had been taken to keep rats from leaving this ship, and it was believed that none of the animals had escaped. The crew were kept under medical inspection and the vessel was disinfected and allowed to depart. A fatal case occurred at Cardiff in Wales in a man who had been employed in gathering up dead rats and destroying their bodies, but where the rats came from and how they had contracted the plague are mysteries. From these various items of plague news it is evident that the disease is still active, and that great watchfulness is required to meet it.

Astereognosis.—At a recent meeting of the Philadelphia Neurological Society an interesting paper on this subject, written by Dr. Walton and Dr. Paul, of Boston, brought out a discussion of this rather obscure symptom of nervous disorder. The term itself is derived from two Greek words, meaning a knowledge of solid objects, and, in its negative form, is meant to apply to that peculiar loss of the ability to recognize the shape, size and locality of a solid body which is displayed by some patients in certain forms of cerebral disease. In attempting an analysis of this subject, as was pointed out in this discussion, the clinician should begin by recognizing the fact that there are certain elementary properties of the sensory nerve cell which we generally speak of as the various modes of sensation, or the pain, tactile, and thermal senses. These elementary properties are probably inherent in every sensory nerve cell. In the lower forms of life we have every reason to believe that they are all present. When we come to the higher animal forms, in which there is elaborated a complex psychological life, we have a much more complex matter to deal with. We have here to consider the activity of the brain

cortex, and we must recognize certain psychological problems more complex than those that are presented by the sensations of pain, heat and cold. It requires quite an elaborated psychological perception to apprehend the qualities of a solid body, such as its size, shape and location in space; and it is not probable that among the very lowest forms of life there can be any such conception unless in a very rudimentary way. In the higher forms of life, these conceptions are not only present but are essential.

This is, therefore, a psychological and physiological as well as a pathological question. Looking at it from the practical standpoint of pathology, we have very good grounds for knowing the course in the spinal cord for these elementary qualities of sensation, such as the pain, tactile and thermal modes of sense. We know that they run in different tracts through the cord. These facts have been proved in certain cases by pathological conditions, as, for instance, syringomyelia and traumata of the cervical region of the spinal cord.

When, however, we come to lesions of the cortex or of the cerebral hemispheres, then we come into the region where there is necessarily present the "gnosis," the knowledge or judgment; and in such cases the disturbances of sensation may present highly complex problems.

A rare form of aphasia, which has occasionally been seen, illustrates this fact. A woman, for instance, could not name an object which was presented to her sight, but if the object was placed in her hand she would name it instantly. In this case there was evidently a breaking up of the fibers that proceeded to the speech-center by way of the visual sense, but the fibers that approached by way of the stereognostic sense remained intact.

In a case of brain tumor reported by Dr. Mills and Dr. Keen, a diagnosis of a tumor in the superior parietal lobule had been made. This diagnosis was based in part on the fact that there was here a peculiar form of incoordination due to a sort of astereognosis which was practically identical with what had been seen in a previous case in the wards at Blockley, in this city, and shown by autopsy to be due to a lesion in the superior parietal lobule. It would not be proper to assert that the superior parietal lobule is the seat of all astereognostic symptoms, but a number of cases have been seen in which astereognosis, associated with a form of incoordination, has been caused by a lesion of this region of the brain. The case of Dr. Mills and Dr. Keen had been of extraordinary interest, because it was a practical, pathological demonstration of some of these rather fine distinctions.

Literary Piracy.—The *Indian Medical Record* possibly thinks that it is published so near the antipodes that it can safely rifle the columns of THE PHILADELPHIA MEDICAL JOURNAL without being detected.

Living on the other side of the earth, the *Record* stands constantly on its head, and may therefore naturally have a perverted view of morals in general. It printed verbatim, on January 30, 1901, Dr. Howard A. Kelly's paper, "On Methods of Teaching Gynecology," which was first published as an original article by this JOURNAL on September 1, 1900; but the *Record* omitted to mention this latter fact. Again, in its Volume XX, February 6, 1901, it published Dr. A. O. J. Kelly's paper on the "Relation between Cardio-vascular and Renal Disease," as an original article without giving us credit for having originally published this paper on October 27, 1900. There is an old saying that imitation is the sincerest flattery, and there is also an old fable about a Spartan boy being blamed not for stealing a fox but for being caught at it. The *Indian Medical Record* can now sympathize with that Lacedæmonian youth.

The Influence of Climate on the Evolution of Experimental Pleuropulmonary Tuberculosis.—Lannelongue, Achard and Gaillard (*Gaz. Heb. de Méd. et de Chirur.*, January 31, 1901, 48me Année, No. 9) have experimented by inoculating into the pleura of 300 male guineapigs, equal quantities of an emulsion of tuberculosis and immediately submitting groups of equal numbers to different climatic influences. The conditions of the injection were in all cases the same and the conditions of lodgment and food in each group were as nearly alike as possible. Two series of experiments were made. In the first series 150 guineapigs were divided into 3 groups. One group was kept at the laboratory of External Pathology of the Faculty of Medicine, at Paris, another group was sent to the seashore at Grandes-Dalles, and the third group was sent to the country at Valmont. In the second experiment, one group was retained at the laboratory, a second group was sent to the mountains, and the third group to a forest on the Isle-Adam. In the two experiments the groups retained at the laboratory presented the advantage of condition, in spite of the apparent unfavorable surroundings produced by lack of space, poor ventilation, absence of light, the high degree of humidity, and the abundance of ammoniacal vapors. Cold and change of temperature appeared to have acted unfavorably, while the equality of temperature and the greater quiet in the laboratory animals seemed to have operated favorably. The evolution of the lesions in the animals of each group presented great variations. While certain guineapigs died of tuberculosis at the end of 6 weeks, in certain others at the end of 15 or 18 months, the lesions were very few and small and were entirely localized to the thorax. This was the end of the experiment in 3 animals of the group sent to the seashore, 3 of the group sent to the country and 4 of the laboratory group of the first experiment. In the second experiment the same condition was found in 1 animal sent to the mountains and in 3 of those kept in the laboratory. Whether or not the remarkable resistance of certain guineapigs to the generalization of tuberculous lesions might go on to complete cure and to the disappearance of virulence is doubtful. These experimental facts have certain definite relations to conditions observed in human pathology. The evolution of tuberculosis in man is eminently variable according to the subject and very diverse forms of the disease are met with independent of climate or of altitude. Cure and resistance to infection are observed with greater frequency in man than in the animals experimented upon. This observation is explained sufficiently by the fact that the guineapigs received a larger dose of the virus, and by the fact that this animal presents a high degree of susceptibility to the infection. [J.M.S.]

Correspondence.

PAROTITIS IN PNEUMONIA.

By T. C. MORRIS, M.D.,

of Lynch, Va.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE noticed in the past few months a limited number of cases of parotitis reported, complicating pneumonia. I wish to add one to the list. The patient was a man, 79 years of age, who was taken with the grip. Four days later bronchopneumonia set in. Five days from the onset of the pneumonia I noticed the patient constantly placing his hand near his left ear, and examination revealed the presence of a parotitis of the left side. The patient made no complaint of it owing to his mental condition, which was very bad at this time. There was no rise in the temperature, which ranged from 99 to 101. But there was a marked change in the character of his pulse which, prior to this, had been remarkable, ranging from 90 to 100, full and strong. Now it ranged from 130 to 140, soft, compressible, and intermittent. There was no appreciable change in any of the other symptoms.

The case terminated fatally 6 days later. Whether the parotitis had anything to do with the change in the circulation I am unable to say.

PULMONARY TUBERCULOSIS AND THE BOARD
OF HEALTH.

By WM. M. CAPP, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

BEFORE the Board of Health should be so unwise as to require the registration of all cases of pulmonary tuberculosis, it should first clearly appear that some practical benefit will thereby be gained to the public. Registration of itself is an idle form and does not give as useful information as the physician's usual death-reports. In New York, where this requirement is in force, no public action other than the registration is taken as to private houses and in cases reported by private physicians. To this extent, at least, registration, then, has no value whatever; and besides, it may do much harm to the individuals reported and their friends. To be of value in protecting public health a registry of consumptives' names should be an open book and proclaimed abroad to all for their personal safety; for, certainly, registration must be thought of as devised for the protection of the public rather than of the patient. But this public exposure of private distress is an idea so shocking to all sense of propriety and humane sentiment that we are told the register is to be kept with the utmost secrecy. Registration, as such, therefore, can accomplish nothing in the way of protection to the public health. A knowledge of the particular house or locality in which germs of consumption exist is what the public authorities really need, and that only, if it is the *bona fide* intention to follow the matter up by officially conducting effective sanitary measures by destroying the threatening germs of the disease wherever they may be found. In fact, prompt and thorough disinfection of infected abodes of the ejected bacillus of consumption is the only paternal intrusion of the government upon individual rights which is called for in these cases, or which will be in any sense valuable for the protection of the public. And this should not be undertaken until liberal and sufficient arrangements for the efficient

prosecution of the work are mapped out and provided for. Disinfection is a more or less costly operation and needs to be done aright by properly qualified agents, and will not be strictly attended to if left in the hands of the average landlord or tenant of means, and cannot be exacted of the poorer tenant, who often lives in quarters most requiring it. The public authorities should not proceed against the individual, but against the disease, in infected premises. Meanwhile, let the health boards also prosecute a more vigorous and intelligent campaign of education and enlightenment of the public upon the nature of the disease under consideration and the proper means to prevent its spread among the people, among whom, in the very nature of things, the unfortunate victims of the disease must associate with more or less freedom.

TWO CASES OF PAROTITIS COMPLICATING
CROUPOUS PNEUMONIA.

By D. J. MILTON MILLER, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

APROPPOS of several cases of parotitis complicating pneumonia, which appeared in your correspondence columns last winter (1900), and of the case of bilateral parotitis reported by Dr. Eshner in your issue of February 16, 1899, I desire to briefly record two additional instances of this unusual complication of croupous pneumonia, occurring in my service and in that of my colleague, Dr. D. D. Stewart, at the Episcopal Hospital, during the winter and spring of 1900. My case was that of a young woman of 18, who, while at the height of an attack of chorea, the last of many similar outbreaks, was seized with acute croupous pneumonia, limited to the whole of the upper and adjacent portion of the middle lobe of the left lung. The disease ran a severe course, with high temperature (104° to 105° F.), intense delirium, and great restlessness, the patient's limbs and body being constantly tossed from side to side by the exaggerated choreic movements. In addition, there was a loud, blowing, systolic murmur, heard at the apex and transmitted to the axilla and to the left scapular angle. The second pulmonary sound was sharply accentuated. These signs were regarded at the time as indicating an associated endocarditis. On the ninth day, while the constitutional and local symptoms were abating (the temperature fell by lysis), enlargement of the left parotid gland was observed. Suppuration rapidly supervened, necessitating incision and free drainage three days later. Bacteriological examination of the evacuated pus gave a pure culture of the staphylococcus aureus. With the establishment of drainage the temperature, which had risen with the onset of the parotitis, fell almost to normal (98.5° to 99°), and continued so until the seventeenth day, when it again arose, owing to the development of an empyema in the right pleural cavity. Aspiration was performed on the twenty-third day, and a pint of thick, creamy pus removed, from which a pure culture of the streptococcus pyogenes was obtained. After this the patient gradually sank into a typhoid condition, and died on the twenty-seventh day. No autopsy was permitted. The leukocytes, which on admission numbered 17,000, increased with the parotitis to 27,000, then fell almost to normal, to rise again to 18,000 at the height of the empyema.

The second case (reported through the courtesy of Dr. Stewart), a woman of 71, on the eighteenth day of an acute pneumonia of the left upper lobe, while the temperature was

falling and the other symptoms abating, developed a left-sided parotitis, which quickly suppurated, and was opened and drained four days later. The wound healed readily in about 10 days, and the lung cleared up entirely, but a severe cystitis developed and she died on the thirty-seventh day. No autopsy could be obtained, nor was a bacteriological examination of the parotid pus made. The leukocytes, at the height of the parotitis, numbered 22,000. The association of the first case with endocarditis is worthy of note in view of the statement of Osler that parotitis in pneumonia is commonly accompanied by this form of heart disease. About one year ago, however, when I looked this matter up with the intention of publishing a more elaborate paper in connection with these cases (the material for which has since been lost), I did not find the associations at all frequent. Another point of interest in the same case is the different bacteriology of the two suppurative processes, the parotitis giving a pure culture of the staphylococcus, while in the empyema the streptococcus only was found, the pneumococcus not being present in either. This does not necessarily indicate that the pneumonia was of streptococcal origin, as in pneumonias, owing to a mixed infection, the streptococcus alone may find access to the pleura. The presence of the staphylococcus in the parotid pus, however, may be regarded as an evidence that the infection reached the gland by way of the parotid duct, as is usually the case in one-sided parotitis. In the bilateral variety, as in Dr. Eshner's case, it is more likely that the inflammation is induced by an infection through the blood.

THE TREATMENT OF PURULENT ENDOMETRITIS BY INJECTIONS OF IODOFORM-GLYCERIN EMULSION.

By JAY G. ROBERTS, M.D.,
of Hastings, Nebraska.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In presenting this article I wish simply to call attention to a new application of that old and tried remedy, iodoform.

It is possible that this method of treatment may not be entirely new, but a careful perusal of all the literature at my command fails to disclose any reference to such a method of treatment of endometritis.

I have always been a firm advocate of iodoform in the treatment of all those conditions attended with pus formation, in spite of its unsavory odor, which has led into many a vain experiment with other numerous substitutes with which the market is flooded, for all of which are claimed all the advantages with none of the disadvantages of the drug which they seek to replace.

After having gone the rounds, I have yet to find a drug which will clear up a suppurating surface and replace foul, unhealthy granulations so well, and in so short a time as iodoform.

The possibilities of such a method of treatment were first suggested by a consideration of the close resemblance of the infected uterine cavity to a tubercular or other abscess cavity, the custom of which it has long been to treat by injections of iodoform-glycerin emulsion. Other methods having given such unsatisfactory results as almost to lead to despair, I determined to put it to a test.

The method of application, which is very simple, is as follows: An emulsion is prepared according to the following formula, the small amount of creolin very effectually disguising the odor without affecting its efficacy to which most patients object very strenuously.

R.—Iodoform	2.00.
Amyl	1.00.
Mix and add	
Glycerin	20.00.
Water	12.00.
Creolin	.80.
M. Stirring gradually, heat to about 27° F.	

This makes a more stable emulsion than that made by the usual method.

For the injection the ordinary long-nozzled intrauterine syringe may be used. I have found a small glass syringe with a soft rubber nozzle, some two inches in length, and of sufficient firmness to answer admirably.

The cervical canal in these cases being quite patulous, as a rule, little difficulty is experienced in inserting.

The patient is placed in the dorsal position with the hips well elevated.

The cervix is exposed by means of the ordinary bivalve speculum, and with dressing forceps and pledgets of absorbent cotton, all discharge is carefully wiped from the cervix and vaginal fornices, which are then thoroughly mopped with sinol or other antiseptic, and then with hydrogen dioxide.

About 4 cc. of the emulsion is then drawn into the syringe, all the air expelled, the nozzle gently inserted well up into the uterine cavity, and the emulsion slowly injected. The syringe is withdrawn and the cervix plugged with absorbent cotton.

It is a good plan to have the patient retain her position for a few minutes before arising, thus keeping the fluid in more prolonged contact with the upper portion of the uterine cavity.

As high as 8 or 10 cc. may be used at a time, but it is better to start a smaller amount, even as low as 2 cc., and gradually increase the quantity to guard against any susceptibility or idiosyncrasy to the action of the drug, the uterine mucosa, as is well known, possessing great absorbent properties. The injections should be repeated every other day or every third day.

The following case, the first in which I had occasion to resort to this method, well illustrates its efficacy. I have since used it in numerous cases of both simple and purulent endometritis with uniformly satisfactory results:

CASE.—Anna T., age 21, waitress. Came under treatment September 21. History of painful menses, constant dragging pain in the pelvis, and leukorrheal discharge.

Examination revealed a somewhat enlarged and painful uterus. Cervix enlarged, everted, and eroded. Red and painful, bleeding readily, with an abundant, thick, purulent discharge.

Applications of iodized phenol were made to the uterus with tampons of ichthyol and glycerin to the cervix every other day, and hot vaginal injections twice daily.

Under this treatment the acute symptoms rapidly subsided, but the discharge continued with little decrease in amount. At the end of 6 weeks silver nitrate applications were substituted for the iodized-phenol with no benefit. Discharge increased in amount.

November 3. Curetted lightly and douched out uterus, which seemed only to aggravate the disorder.

November 18. Injected 4 cc. iodoform-glycerin emulsion.

November 20. Discharge less abundant. Injected 6 cc. iodoform-glycerin emulsion.

November 22. Discharge markedly diminished. Treatment continued.

November 28. Discharge absent. Cervix almost normal in appearance.

December 6. Discharge absent for over a week. Cervix normal. Consistency not painful.

Patient has been seen at intervals since, and has been entirely free from discharge, pain, or other symptoms. Menses regular and painless.

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA.

Chester Hospital.—A nurses' home and laundry will be built as an addition to the Chester Hospital.

Dr. B. A. Randall Resigns.—Dr. B. A. Randall has resigned the position of Eye and Ear Surgeon to the Methodist Hospital. Applicants, who must possess the B. A. degree, should communicate promptly with the Board of Managers.

Death of Dr. Emil Schnizler.—After two weeks illness Dr. Schnizler died at his home in Philadelphia on March 6. He had practised in this city for twelve years and had devoted considerable time to the study of rheumatism and gout. He was born at Frankfort-on-the-Main, Germany, and received his medical education at Heidelberg University. On graduating there, in 1868, he became head professor at the Vienna Hospital, where he remained for fifteen years.

University of Pennsylvania Medical Bulletin.—We note that the changes in the *University Medical Magazine*, which were announced in February, appear with the March issue. The title has been changed to read **University of Pennsylvania Medical Bulletin**, the reading matter is printed in double instead of single column, and, what is particularly creditable, all advertising matter has been excluded. The policy and scope of the publication are in no way affected by these changes, as it still continues to be the official organ of the Medical Department of the University of Pennsylvania. In its present form the publication is both attractive and dignified in appearance.

Nurse Obtains a Mandamus.—Miss Mariane H. Wood, a nurse at the Pennsylvania Hospital, was awarded an alternative writ of mandamus returnable March 25, compelling the Pennsylvania Hospital to reinstate her as nurse in that institution. Miss Wood was admitted to the Pennsylvania Hospital Training School for nurses on March 28, 1898, and it is reported that before her term of three years was completed, she was expelled on August 15, 1900, for slapping a patient. The nurse claims that she had received peremptory instructions to keep a powerful colored woman who had undergone abdominal operation on her back, and that the patient resisted by clutching the nurse's hair threatening to do herself injury. The impact of the nurse's hand against the patient's cheek in the attempt to keep the latter in a recumbent position is the "slap" which she says she is accused of inflicting.

The Sesqui-Centennial of the Pennsylvania Hospital.—The 150th anniversary of the founding of the Pennsylvania Hospital in this city will be celebrated in May of this year. On the 15th of that month an address will be delivered by Mr. John B. Garrett in the new assembly room in the old Pine Street institution. On the 18th of the month the contributors and invited guests will enjoy a visit to the department for the insane in West Philadelphia. The committee having charge of the anniversary is composed of Mr. Benjamin H. Shoemaker, chairman; Mr. John B. Garrett, Mr. J. Stewart Jenks, Dr. Thomas G. Morton, and Dr. John B. Chapin. The Pennsylvania Hospital is one of the most important and interesting of our pre-Revolutionary institutions, and its coming anniversary will doubtless attract wide attention. The occasion, it is hoped, will be a great success.

Obstetrical Society.—DR. GUY L. HUNNER, of Johns Hopkins Hospital, by invitation addressed the meeting of March 7. Dr. Hunner gave a thoroughly practical talk on **Streptococcus in Gynecology**. The localized forms of this infection were the types discussed. The various foci of infection, within the uterus, in the perimetrial tissues, etc., and the modes of infection were detailed and histories of cases given. Most of the infections from the uterine contents occur not through the medium of the tubes but through the uterine wall. Hence abscesses may be found anywhere in the pelvis. The diagnosis of streptococcal infection is considered to be sufficiently easy to render a mistake inexcusable. The history of the case is of the greatest importance in diagnosis, as streptococcal infection is almost always connected with the puerperium. Examination then confirms

the diagnosis which can be at least provisionally made from the history alone. Streptococcal infections are usually cellulitic in character. When operating to evacuate abscesses a cardinal rule to be observed is to keep out of the peritoneal cavity. The inguinal incision should be used, thus avoiding the peritoneum, or vaginal puncture anterior or posterior to the uterus. DR. WILMER KRUSEN spoke of the conservative operations of the present day and their efficacy in preserving the functions of the patient. The possibility of the reaccumulation of pus if only a vaginal puncture was made was mentioned. He asked Dr. Hunner if antistreptococcal serum was used at the Johns Hopkins Hospital and also how streptococcal was differentiated from gonorrheal infection. DR. HUNNER stated that antistreptococcal serum had been used but it is not considered of much value. Many cases get well without it and a favorable change may occur almost synchronous with its use and yet not be due to its effect. The user must be careful in drawing conclusions. Regarding the inefficiency of puncture to fully drain abscess cavities it was stated that when the abscess is between the uterus and bladder an incision is made; when posterior to the uterus or laterally a puncture is made and then enlarged by dilators. No irrigation is used in these cases, the operation being done by the dry method. Streptococcal and gonorrheal infections cannot be differentiated except by the history of the case. The subject was also discussed by Drs. DOWNES, ROSENTHAL, WILSON, HIRST, BOYD, and NASSAU.

DR. A. J. DOWNES read a paper on **Spinal anesthesia in cases strongly contraindicating general anesthesia**. Five cases, including a gastroenterostomy, two hysterectomies, and an extrauterine pregnancy were reported. The results warrant the use of this method in selected cases. DR. GEORGE ERETY SHOEMAKER stated that until surer methods of sterilizing the anesthetic were in use it was wiser to retain the old anesthetics. Very few cases will not bear general anesthesia. DR. FRANK HAMMOND expressed the same view. General anesthetics, particularly chloroform and oxygen, can be used in practically every case which may seem to contraindicate them.

Vital Statistics of Philadelphia for the week ended March 9, 1901:

	CASES.	DEATHS.
Total mortality		495
Inflammation of appendix 1, bladder 1, brain 11, bronchi 9, heart 2, kidneys 15, larynx 1, liver 1, lungs 80, pericardium 1, peritoneum 6, pleura 3, stomach and bowels 17, spine 2		150
Inanition 9, marasmus 13, debility 9		31
Tuberculosis of lungs		77
Apoplexy 14, paralysis 5		19
Heart—disease of 33, fatty degeneration of 3, dropsy of 1		37
Uremia 10, diabetes 3, Bright's disease 10		23
Carcinoma of colon 1, breast 2, stomach 7, uterus 2, liver 1, pancreas 2, rectum 2		17
Convulsions		14
Diphtheria	68	9
Brain—congestion of 1, disease of 1, hemorrhage from 1, softening of 4, tumor 2		9
Typhoid fever	85	6
Old age		6
Cyanosis		6
Scarlet fever	29	5
Influenza 9, abscess, back 1, abortion 2, alcoholism 1, asthma 3, anemia 1, atheroma 1, burns and scalds 3, casualties 7, congestion of lungs 5, cirrhosis of liver 2, membranous croup 2, erysipelas 2, fracture of skull 1, gangrene of foot 2, intussusception 2, indigestion 2, jaundice 1, neuralgia of heart 4, obstruction of bowels 1, edema of lungs 3, purpura hemorrhagica 1, rheumatism 1, sclerosis of liver 1, surgical shock 1, septicemia 3, suffocation 1, suicide 3, teething 2, tumor, uterus 1, neck 1, ulceration of stomach 1, whooping-cough 3		74

NEW JERSEY.

Beverly.—Scarlet fever has again made its appearance at Beverly, and all cases are being quarantined.

Muhlenberg Hospital.—A plot of ground with a frontage of 500 feet and 300 feet deep has been given to the Muhlenberg Hospital at Plainfield by James A. Martine. The value of the land is estimated at \$10,000.

Quarantine Removed.—For the first time in 2 weeks the churches and schools were again opened in Woodbury. Vaccination is being enforced.

Medical Library.—The medical and surgical library of the late Dr. William Pierson, of Orange, numbering 8,000 volumes, has been presented by Mrs. Pierson to the physicians of Orange, who have decided to organize the William Pierson Medical Library Association.

NEW YORK.

Acquitted.—The nurse in Bellevue Hospital who was charged with having been responsible for the death of one of the insane inmates, has been acquitted.

Changed to a Periodical.—The Annual Circular of the New York University will now be issued twice a month as a periodical containing in addition recent progress in the university.

New Scientific Quarterly.—A new scientific bulletin under the title of *New York University Bulletin of the Medical Sciences* will appear for the first time this month, edited under the auspices of the New York University Medical Society.

Nurses' Home.—Plans were filed for the nurses' home to be erected for the Presbyterian Hospital in New York. The structure will be 8 stories in height. Several months ago a benefactor, whose name was not disclosed, gave the hospital \$300,000 for the erection of this home, provided the institution would assume the maintenance of it.

Bellevue Maternity.—The Medical College and Dispensary Building of the Bellevue Hospital will be altered into a maternity hospital, dispensary and dormitory. The expense for altering the interior of the building has been estimated at \$20,000. The object of these alterations is to bring about a closer approximation of the various departments of the hospital.

New York Obstetrical Society.—Stated meeting, February 13, 1901. The president, DR. H. J. BOLDT, in the chair.

DR. BOLDT presented a case of **persistent amenorrhea**, the trouble dating back to the time of her first menstruation at the age of 13. Before marriage she menstruated at intervals of 3 or 4 months, since that time (3 years) she has menstruated only twice. The pelvic organs are normal, with the exception that the uterus is slightly smaller than it should be. DR. H. N. VINEBERG remarked that in some cases, after marriage, small uteri seem to diminish in size and lose their function rather than develop, as one might expect.

DR. GEORGE L. BRODHEAD reported a case of **cesarean section for fibrocystic uterine tumor**. The specimen here presented is one of fibrocystic growth of the uterus, removed from a patient upon whom the operation of cesarean section was performed February 2, 1901, 11 days ago. The history of the case was as follows: The woman first came under my observation on November 20, 1900, when she presented herself for examination in the lying-in service of the New York Postgraduate Hospital. The patient was 34 years of age, she had been married 2½ years, and her menstrual history prior to marriage and up to the time of the present pregnancy had been normal in every respect. There have been no symptoms at any time of uterine growth, and her general condition was very good. The last menstruation had begun on May 6, and had continued for 3 days, the usual amount of blood having been lost. Abdominal examination showed a uterus enlarged to the size of about 7 months' gestation, the fundus being higher than it should have been to correspond to the period of pregnancy as based upon the date of the last menstruation, namely, 6 months or a little over. The presentation was vertex, the head being high above the brim, and the position left occiput anterior. The fetal heart-rate was 148, and a loud uterine souffle was heard in the right upper quadrant. The pelvis was justo minor, the woman being of small stature, about 5 feet 2 inches in height, and weighing about 109 pounds. Vaginal examination revealed a tumor the size of an orange, of moderately firm consistency, well down in

the culdesac of Douglas, pressing the cervix well forward behind the symphysis. Thinking that the tumor might be one of the ovary, or a pediculated fibroid, which might be made to slip back into the abdominal cavity, the patient was placed in the knee-chest position, but the growth was so adherent that it could not be replaced. The patient was extremely anxious to have a living child, and therefore section at or near full term seemed indicated. Dr. Dudley, who very kindly saw the case with me, concurred both in the diagnosis of fibrocystic growth, and the advisability of performing cesarean section. On January 19, the position was found to be left sacro-anterior, the breech being well above the brim, and a loud, umbilical souffle was heard in the left lower quadrant of the uterus. On February 2, 1901, the operation was performed at the New York Post Graduate Hospital, the patient being within 10 days of full term. It seemed best to elect this time, for the reason that the child was of good size, and the uterus already well distended. In the operation, able assistance was rendered by Dr. Dudley and the house staff of the hospital, Doctors Boldt and Ward being present also. The technic of the section was that described by Dr. Dudley in the *New York Medical Journal* of November 3, 1900, in his article "The Modern Cesarean Section. An Ideal Method of Treatment for Placenta Previa." Under constant irrigation with a hot normal saline solution, an incision 6 inches in length was made in the median line, from a point just below the navel to just above the symphysis, and the uterus exposed. A rubber ligature was then passed over the fundus, and carried down to the lower segment of the uterus, just above the fibroid. While the uterus was held up and the ligature tightened by an assistant sitting between the legs of the patient, and while the abdominal walls were kept closely applied to the uterus above, an incision about 6 inches in length was quickly made through the uterine wall and the fetal sac opening. The breech of the child, found lying just beneath the incision was seized, the child lifted out and the cord clamped and cut. The amount of amniotic fluid was small. The uterus was followed down, and lifted out of the abdominal cavity, while the intestines were protected above. The child, a male, weighing six pounds seven ounces, was born five minutes after the operation was commenced, in good condition, and soon cried lustily. The placenta was found lying loosely in the uterine cavity, and was removed with its membranes, manually. The tumor was adherent to the rectum, but the adhesions were soon separated, and the growth lifted up out of the abdominal cavity. It was then found that during its removal, the cyst had ruptured, allowing a small quantity of yellowish brown fluid to escape. The mass was about the size of an orange, and was attached to the posterior wall of the uterus by a thin pedicle about 1½ inches in width. The growth was enucleated and the uterine wall closed with several layers of fine catgut sutures. Ten minutes had been occupied in the removal of the fibroid. A finger was then passed through the cervix from the uterine side, and the incision closed in layers with a continuous suture of fine No. 1 ten-day chromicized catgut. Beginning above, the mucosa was first closed, then from below upward, the muscular layer, and finally the peritoneal coat united. The ligature was now loosened, and several sutures passed to control slight oozing. As there was a moderate amount of bleeding from torn adhesions, a strip of iodoform gauze was placed in the culdesac, and the end drawn out of the vagina. The incision in the abdomen was closed in layers with catgut, and the patient put to bed in excellent condition, a little less than an hour having been consumed in the entire operation, and the blood loss having been very small. The child was well developed, and since birth has done well. The mother's recovery has been uninterrupted from the first. I take this opportunity to thank Dr. Dudley and the house staff for their valuable assistance and kindly interest in the case. DR. VINEBERG asked if it would not have been feasible to remove the growth per vaginam. DR. BRODHEAD stated that the patient was a primipara, 35 years of age, exceedingly anxious to have a living child and perfectly willing to undergo the operation at full term. Under these circumstances it seemed best to wait, as operation per vaginam would almost certainly have induced premature labor with the probable loss of the child.

DR. E. H. GRANDIN read a few Notes relating to cases of **ectopic gestation**. Dr. Grandin gave a most interesting talk on this subject, relating the clinical history of

many of his cases, seen both in his own and in consultation practice. It falls to the lot of comparatively few men to possess such a wealth of material from which to draw deductions which will be helpful to those interested in this most absorbing subject. His experience teaches him that many of the patients with whom he had to deal, give histories which are decidedly atypical, judging by the classic symptoms spoken of in the majority of textbooks. Dr. Grandin believed that when in doubt, it was advisable to make a posterior incision in the culdesac, for the purpose of establishing the diagnosis. The abdominal section could then be resorted to for the removal of the mass, if the posterior section were insufficient for the purpose. DR. GEORGE T. HARRISON in discussing the paper said that he thought the reader of the paper should have made a clearer distinction between cases where the ovum is dead, and those in which the ovum is living. In the latter class of cases, the extreme softness of the tumor lying near the uterus was a very characteristic symptom. Again, where the ovum is dead, the uterus is hard, whereas if the ovum is living the uterus is usually soft. He believed all cases of ectopic gestation should be attacked through the abdominal wall, and not by a posterior colpotomy. He thought that the rupture of the tube was a rare termination, while tubal abortion is a frequent termination. At least 80% of the cases terminate that way. After death of the ovum the picture changes, and the tumor becomes harder. He strongly advocated the abdominal section for such cases. DR. H. N. VINEBERG thought that in certain cases the incision in the culdesac for the purpose of diagnosis was a valuable one. In one instance he had removed a cystic ovary in that way where ectopic pregnancy was suspected. He believed that Dr. Mann had reported a case in which he lost the patient by making an incision in the culdesac. The patient bled so profusely that before he could find and catch the bleeding vessel, the patient died. In the second case, the right tube was removed by posterior section and bleeding was so great from the whole surface of the cavity where the mass had been lying that it was necessary to pack the cavity. Bleeding continued and it required very thorough tamponing to arrest the hemorrhage. After this she did well, but the case emphasized the point that the lower route is not a safe one through which to remove a tubal pregnancy. In the third case, the patient had been curetted twice, it being supposed that the case was of incomplete abortion. Dr. Cleveland diagnosed the condition as that of ectopic pregnancy and on operating he found an unruptured tubal pregnancy of $3\frac{1}{2}$ to 4 months. In removing the tube he had used Skene's electric clamp, for he prefers it because of the liability of ligatures to cut through the soft tissues. The patient recovered. DR. A. BROTHERS said that the pregnancy of ectopic gestation was to him alarming. He had had a case some weeks before in which the mass was so bound down by adhesions that it was necessary to remove the uterus. The patient made a good recovery.

NEW ENGLAND.

Donation.—The Yale Medical School, New Haven, has received an anonymous donation of \$100,000 to be devoted to the construction of a building consisting of a laboratory of clinical medicine and surgery.

Change of Meeting.—The State Medical Association of Maine, on account of the conflict of dates with the meeting of the American Medical Association, has changed the time of its annual session to June 12 to 14.

Donation to Anna Jaques Hospital.—The Anna Jaques Hospital, Newburyport, which for some years has been seriously cramped for room, will have a new and commodious structure through the munificence of the Hon. William C. Todd. The trustees received a letter from Mr. Todd in which he makes the offer of \$50,000 for a new building, and also offers as a gift a slightly and commodious site, valued at \$5,000. The trustees, in acknowledging the gift, state that the difficulty of providing better accommodations has long perplexed them, and that no gift would have been more generally and deeply appreciated than this. The gift will be used solely for the erection of a new building.

Hospital Site Proposed.—There appears to be considerable controversy among the citizens of Roxbury relative to the establishment of a hospital for consumptives on grounds in Marcella Street. The following resolutions were adopted and a committee appointed to wait upon the Mayor:

Whereas, the Mayor in recommending the transfer to the board of health department of the Marcella Street Home, Roxbury, for the purposes of a hospital for consumptives, and, whereas, the said property is unfit for such use, because of its unhealthy location, its low level, its proximity to a large city stable and its unsanitary condition, besides being a menace to the health of nearby residents and a cause for the decrease in the value of surrounding property; therefore,

Resolved, that, while we are heartily in favor of a hospital in the proper place, we are opposed to the site of the Marcella Street Home for such purpose.

Resolved, that we request the members of the city government to oppose this proposed location for a consumptives' hospital.

CHICAGO AND WESTERN STATES.

Appointment.—Dr. Z. T. Martin, of Lathrop, Mo., has been appointed physician to the penitentiary at Jefferson City, Mo.

Fined.—A magnetic healer of Moline, Ill., was fined \$100 and costs for practising medicine without a license. He refused to pay the fine and was committed to jail.

Death of Dr. Fernand Bazan.—It is reported that Dr. Fernand Bazan, a prominent physician who practiced for many years in San Francisco, died in Glion sur Montreaux, Switzerland, on March 6.

Smallpox in Kansas.—Doctor W. B. Swan, secretary of the State Board of Health, issued a bulletin stating that there are more than 1,000 cases of smallpox in the State. The worst infected district is Crawford and Cherokee counties. In these two counties there are not less than 500 cases of the disease.

The Western Ophthalmologic and Otolaryngologic Association will meet in its next annual session in Cincinnati, Ohio, April 11 and 12. A fine program has been arranged and the medical profession are cordially invited to attend the sessions. Dr. C. R. Holmes, of Cincinnati, is chairman of the local committee of arrangements. Dr. M. A. Goldstein, of St. Louis, is the president, and Dr. W. L. Ballenger, of Chicago, is secretary.

Bequests to the University of Michigan.—Mrs. Love M. Palmer, widow of Dr. A. B. Palmer, who was professor in the medical department of the University of Michigan from 1852 up to the time of his death, 15 years ago, died March 8. By the term of her will, she leaves \$85,000 to the university. It is understood that \$20,000 will go to build a new ward for the hospital, and \$15,000 to maintain free beds in that institution. Mrs. Palmer left \$10,000 with which to build a tower for St. Andrew's Episcopal Church in Ann Arbor, Mich.

Bubonic Plague in California.—The commission selected by Secretary Gage to investigate the plague situation in behalf of the Government has returned to Washington, but their report as yet has not been published. The commissioners are Prof. F. G. Nery, Prof. Simon Flexner, of the University of Pennsylvania, and Prof. L. T. Barker; the other commissioners being also attached to institutions of learning. They are in no way connected with the Federal service and were chosen because of their recognized ability as experts. The committee of citizens of San Francisco that had been in consultation with the Treasury Department regarding the bubonic plague in that city deny that the health affairs of San Francisco have been taken charge of by the Surgeon-General's Department. They furthermore state that the death list in Chinatown is now lower than it has been for years.

SOUTHERN STATES.

Buxley Professorship.—The professorship endowed several years ago by Dr. Henry Willis Buxley, of Baltimore, has been designated "the Buxley professorship of pathol."

ogy." The present incumbent is Prof. William H. Welch of the Medical School.

Charity Hospital.—An unconditional donation of \$50,000 has been received by the Charity Hospital, New Orleans, from an unknown source through Dr. Rudolph Matas. The money was donated for the purpose of increasing the nursing staff and providing a home for trained nurses.

Verdict of \$7000 for the Loss of an Eye.—In the case of the De La Vergne Refrigerating Machine Company vs. Stahl, in which a verdict of \$8000 was returned, the judge said that he will affirm the judgment if a remittitur of \$1000 be made from the \$8000, as the later is larger than in any discoverable case of a similar nature.

Memorial Tribute.—The Medical Society of the District of Columbia met on March 5 for the purpose of devoting a memorial tribute to the life and character of the late Dr. Samuel Busey. A memoir was read by Dr. W. W. Johnston, giving a sketch of Dr. Busey's life and an appreciative estimate of his life as a man, citizen, and physician.

Death of Dr. John Randolph Page.—Dr. John Randolph Page died at his home at the University of Virginia on March 11 of acute Bright's disease, aged 70 years. Dr. Page was educated at the University of Virginia, being graduated in 1850 with the degree of doctor of medicine, after which he was for some years a student in Paris. He was chief-surgeon in the Confederate service, first with Magruder, on the Peninsula, and afterward in Lynchburg. After the war he practised medicine in Baltimore, and later he became professor in the Louisiana Military Academy. From 1872 to 1882 he was professor of agriculture in the University of Virginia. Resigning his chair he went to Birmingham, Ala., and again entered upon the practice of his profession.

CANADA.

(From Our Special Correspondent.)

To Combine Toronto Medical Schools.—Steps are being taken to bring about the amalgamation of Trinity Medical College, Toronto, and Toronto Medical College. A committee composed of three members of each faculty was appointed to draft a definite basis of amalgamation.

The Medical Alliance of America, now attempting to do business with the medical profession in Toronto, Montreal, and other Canadian cities, has been disapproved of by the Toronto Clinical Society. One year ago the corporation secured a charter from the Dominion Parliament and at once set about exploiting the profession of medicine. The doctor is secured as an ordinary member of the Alliance, the same as any other individual, at the rate of 15 cents per week. He is then appointed by the Company one of the medical advisers of the Alliance. When an ordinary member falls ill, if he wishes to secure the benefits of the Alliance, he must call in one of the Alliance's physicians to attend him. The Company pays the doctor at the rate of \$1.00 per office consultation and \$1.50 for each house-visit paid—that is, if the fund set apart for that specific purpose will permit of such lavish distribution. At the regular stated meeting of the Toronto Clinical Society, on the evening of the 6th inst., the Society unanimously adopted a resolution unfavorable to the methods of the Alliance.

Winnipeg General Hospital has just published its annual report. The number of patients treated in the hospital during the past year amounted to 2,649; and in the out-door department there were 1,435 consultations. Of the in-door patients, 1,684 came from the City of Winnipeg, 785 from other places in the province of Manitoba, 150 from the other provinces and 30 from the United States. In the financial report appeared a deficit of \$4,510.50, which could be accounted for by the fact that the hospital had to contend with an outbreak of smallpox within its walls at the beginning of the year. Reference was made in the report expressing deep regret at the death of one of the nurses, Miss Lynch, who had contracted the disease while in the discharge of her duties; and also to the generosity of the Lake of the Woods Milling Company which donated \$2,500 to the institution.

The nursing staff of this hospital now consists of a lady superintendent, 5 head nurses, 1 district nurse and 50 pupil nurses. During the year 223 applications were received for admission to the hospital training school. Of these 23 were accepted on probation and 16 as pupils of the school.

Nova Scotia is to Have a Consumption Sanitarium.—A year ago the Legislature of the province passed a Sanitarium Act and appointed a committee to look into the matter during the recess of the House and make recommendations at an early date. Through sickness and other misfortunes this committee has not been able to report until the present time; and the other day Premier Murray laid before the Legislative Assembly, now in session, the report of the committee. It recommends that a single sanitarium be constructed on the congregate plan, capable of accommodating 20 patients; that no resident medical officer be appointed, but that there shall be regular specified visits made by two properly qualified medical men; that the site be either at Dutch Village near the city of Halifax, or else on the shores of Bedford Basin near the village of Bedford. The committee considers it advisable that any sanitarium for the treatment of consumption should be erected near the large centers of population; and that the Sanitarium Act of the province be amended so as to provide for municipalities wishing to construct and carry on these institutions, may receive aid from the Government. Dr. A. P. Reid, the secretary of the provincial Board of Health, favors the recommendations, but prefers to see a regular medical officer in charge; he also objects to the site on the Atlantic seaboard.

A new civic hospital for Montreal has long been contemplated, but after struggling with this question for the past one or two years, the city is no nearer the goal. Smallpox is even now on the outskirts of the city and there is no place provided for the reception of these patients. The present Civic Hospital is old and dilapidated, in fact, water-logged, has been universally condemned, by both prominent medical men and influential citizens, and even if available, could not be used as it is now full of scarlet fever patients, a disease which has been epidemic in Montreal almost since last September. The old smallpox pavilion contains four beds, and both it and the Civic Hospital are little better than ordinary barns. There are now two propositions before Council for the adjustment of this important question. One is for a single hospital for contagious diseases, to be under civic control, financially, but to be under the medical control of the leading French hospital, the Hotel Dieu, and the leading English hospital, the Royal Victoria. The other proposition favors two hospitals, one for the French and one for the English practitioners. Alderman Ames, who by the way is an advanced hygienist, now favors building one hospital, but so far has been unable to get Council to adopt any plan whatever. The Montreal Medical Society, composed of French practitioners, favors one hospital.

Gynecological surgery among the insane has reached the end of its sixth year in the London, Ont., Asylum, during which time the work has been carried on in a systematic manner, but without much encouragement from the profession or the alienists in Canada. In the annual report on the asylums of Ontario just issued a summary is given of this work. During the year closed 55 of these cases have been operated on. Of these patients, 17 have recovered, 16 have improved, none have died, and so far as yet heard from 22 of the cases are unimproved mentally. It is fully expected that several of the 16 improved will get quite well. During the period of this work at London, 286 female patients have been examined, generally under an anesthetic, and organic diseases have been found in some one or more of the pelvic organs in 243 of them. Only 43 of the entire number subjected to an examination have been found free from pelvic diseases. A total of 564 diseased conditions were found in 226 patients. "In the women's halls the average recovery rate, including cases improved, for the five years, 1886-91, calculated on the admissions, was 37.2%; in the next five years, 1891-95, it was 37.5%. But in the next five years, during which the gynecological work was a factor, that is, in 1896-1900, the recovery rate rose to 52.7%." The chief credit of this work belongs to Dr. A. T. Hobbs, who has recently resigned from the staff to enter private practice.

The operations were never performed merely for the insanity, but always for some actual, existing disease.

Lodge practice in British Columbia about a year ago seemed to be on the wane when the Victoria Medical Society adopted a strong resolution disapproving of the practice and deciding that they collectively and individually should have nothing more to do with it whatever. This of course raised a storm amongst the fraternal societies, and efforts were made to induce practitioners to come from the East, particularly from the province of Ontario, as well as from England. This proved ineffectual, as the Medical Act of British Columbia required that an examination had to be passed before any one could practise in the Pacific province. During the past summer, however, the fraternalists have not been idle. They appointed a special committee to take the matter in hand, and as a result petitions were circulated throughout the province praying that the Government would cancel the Medical Act, and permit of practitioners settling in British Columbia, provided they had an English degree, or a license to practise in any of the other provinces of the Dominion. This proved too much for the Victoria Medical Society, and they are now said to be seeking to propitiate the fraternalists. It would certainly be an indirect act of coercion if the Legislature, before whom the petitions now lie, should grant the prayer of these petitioners; and for the sake of the honor of the profession of medicine in the province of British Columbia it is sincerely hoped that the Medical Society of Victoria will continue to exhibit their Spartan courage.

MISCELLANY.

Scarlet Fever among Yale Students.—Two cases of scarlet fever have been discovered in a Yale University boarding-house.

Fellow Students of Bismarck.—Dr. Mitchell King, who recently died in Charleston, S. C., aged 86 years, was a fellow student of Bismarck, at the University of Göttingen, together with two Americans, John Lathrop Motley and Amory Coffin, of South Carolina. The three Americans ate a Fourth of July dinner at Göttingen in 1832 with Bismarck as their guest. Bismarck said that Germany would be united in 30 years. Coffin disagreed with him and a bet was made of a bottle of champagne which the loser was to carry to the country of the winner and drink with him. Bismarck lost, but as civil war was raging at the time, the whereabouts of Coffin could not be determined.

Obituary.—DR. JOHN B. McDONALD, at Spokane, Wash., on March 3, aged 63 years.—DR. JASON WALKER at Middot, Me., on March 7, aged 66 years.—DR. WILLIAM DAVISON, at Kenosha, Wis., on March 2.—DR. ASA BOWMAN, in Christian County, Ill., on March 6, aged 82 years.—DR. R. L. MAYFIELD, at Marble Hill, Mo., on March 5.—DR. SAMUEL MEGUIRE, at Trenton, Ill., on March 6, aged 76 years.—DR. ALONZO T. SMITH, at Syracuse, N. Y., on March 8, aged 81 years.—DR. JONAS C. RAYMOND, at Oakland, Cal., on March 3, aged 77 years.—DR. WILLIAM STIYES, at Washington, N. J., on March 8.—DR. ROBERT HEATH DODGE, at Bethesda, Md., on March 11, aged 29 years.—DR. J. A. SWARTZ, at Harrisburg, Pa., on March 10, aged 76 years.—DR. R. WILSON CARR, at Sedalia, Mo., on March 4, aged 70 years.—DR. J. D. SCOTT, en route to Villisca, on March 11.—DR. LLOYD ZANER, at Wilkesbarre, Pa., on March 12.—DR. H. B. HALL, at River-ton, Pa., on March 8.

To the Medical Profession of the United States.—The undersigned constitute a committee similar to those formed in several European countries for the purpose of receiving subscriptions for a monument commemorative of the distinguished scientific services of Prof. Leopold Ollier. Among the members of these committees are Lord Lister, Profs. von Bergmann, Czerny, Darante, and other leading men. The municipality of the city of Lyons has dedicated an open space adjacent to quarters of the various academic faculties on the border of the Rhone named in his honor, "Place Leopold Ollier."

The profession of this country are well aware of the great services rendered by Prof. Ollier, especially in the domain of plastic and osseous surgery. His labors have been most

fruitful in the domains of surgery, of physiology, and of pathology.

The committee hopes to raise not less than one thousand dollars (\$1,000) as a testimonial from the profession of America. Checks should be forwarded to W. W. Keen, 1729 Chestnut Street, Philadelphia, Pa., and at as early a date as possible.

Committee.
ROBERT ABBE, New York.
WILLIAM T. BULL, New York.
P. S. CONNER, Cincinnati.
A. T. CABOT, Boston.
HOWARD A. KELLY, Baltimore.
W. W. KEEN, Philadelphia.
RUDOLPH MATAS, New Orleans.

TURKEY IN ASIA:	Japa	Jan. 1-15	Epidemic.	

YELLOW FEVER.			CASES.	DEATHS.
CUBA:	Havana	Feb. 17-24	8	

Doctors Must Not Leave Patient.—The *Medical Record* publishes the following: Dr. P. H. Flood was ordered to pay \$2,000 damages by the Supreme Court recently. Evidence showed that over a year ago he was called to attend Mrs. Margaret A. Lathrop. An operation was deemed necessary by him. Her screams interfered with his application of the necessary instruments. He finally said that if she "did not quit he would quit." And leave he did, although the patient was in agony. The husband followed the physician to the door, begging him not to go. He refused to come back, and it was over an hour before another doctor was obtained, the woman in the meantime suffering dreadfully. The other surgeon performed the operation, saving the mother's life at the expense of that of the child. Mr. and

Mrs. Lathrope sued Dr. Flood and got a verdict for \$2,000 in the Superior Court. Dr. Flood appealed the case to the Supreme Court, and the latter affirmed the lower court's action, saying, in part: "It is the undoubted law that a physician may elect whether or not he will give his services to a case, but having accepted his employment, and entered upon the discharge of his duties, he is bound to devote to the patient his best skill and attention, and to abandon the case only under one or two conditions. First, when the contract is terminated by the employer, which termination may be made immediately. Second, when it is terminated by the physician, which can be done only after due notice and an ample opportunity afforded to secure the presence of other medical attendance. . . . He can never be justified in abandoning it (case) as did this defendant, and the circumstances show a negligence in its character amounting wellnigh to brutality." —[*San Francisco Examiner.*]

Changes in the Medical Corps of the U. S. Army, for the week ended March 9, 1901:

RAND, Captain IRVING W., assistant surgeon, is relieved from duty at Santa Mesa Hospital, Manila, and will proceed to Nagasaki, Japan, for the purpose of establishing a military hospital at that place.

DUTCHER, First Lieutenant BASIL H., assistant surgeon, U. S. Army, is relieved from duty at present station and will report to Captain Irving W. Rand, assistant surgeon, for duty.

PERSONS, First Lieutenant ELBERT E., assistant surgeon, U. S. Army, is relieved from duty at present station, and will report to Captain Irving W. Rand, assistant surgeon, for duty.

STRAUB, Major PAUL F., surgeon, now at San Francisco, Cal., is relieved from further duty in the division of the Philippines, and will proceed to Fort Crook for duty.

THOMASON, Major HENRY D., surgeon, recently appointed, will proceed from Albion, Mich., to San Francisco, Cal., for temporary duty, upon the completion of which he will proceed to Manila, P. I., and report for assignment to duty.

ZOUNER, Major ROBERT H., surgeon, is relieved from temporary duty at Columbus Barracks, and will rejoin his station at Fort Du Pont.

COWPER, Captain HAROLD W., assistant surgeon, recently appointed, now at San Francisco, Cal., will report for transportation to Manila, P. I., where he will report for assignment to duty.

CARR, Major L. C., surgeon, will proceed to Santiago, Cuba, for assignment to duty.

JAMES, H. M., acting assistant surgeon, is granted leave of absence for 1 month, with leave to apply for an extension of 1 month, and to go beyond the limits of the department of Cuba.

KEEPERE, Captain MATTHEW, assistant surgeon, recently appointed, now at Fort Crook, will proceed to San Francisco, Cal., and report for transportation to Manila, P. I., where he will report for assignment to duty.

The following named assistant surgeons, U. S. Volunteers, recently appointed, will proceed from the places hereinafter specified to San Francisco, Cal., and report for transportation to Manila, P. I., where they will report for assignment to duty: Captains JAMES S. KENNEDY, Fort Sam Houston; FRANK P. KENYON, Joplin, Mo.; DWIGHT B. TAYLOR, Columbus Barracks.

Changes in the Medical Corps of the U. S. Navy, for the week ended March 9, 1901:

EAKINS, O. M., assistant surgeon, detached from the "Ajax," when put out of commission, and ordered home to wait orders.

CORDEIRO, F. J. B., surgeon, detached from the "New Orleans" and ordered to the "Buffalo."

SPEAR, R., passed assistant surgeon, detached from the "Buffalo" and ordered to the "Isla du Luzon."

KENNEDY, R. M., passed assistant surgeon, detached from the "Newark" and ordered to the "Bennington."

STONE, M. V., assistant surgeon, detached from the "Isla de Luzon" and ordered to the "Buffalo."

SNYDER, J. J., assistant surgeon, detached from the "Isla de Cuba," and ordered to Pollock, P. I., with marines.

PAYNE, JR., J. H., assistant surgeon, detached from duty at Pollock, P. I., and ordered to the "Isla de Cuba."

HUNTINGTON, E. O., assistant surgeon, detached from the "Bennington" and ordered to the "Newark."

Changes in the U. S. Marine-Hospital Service, for the week ended March 7, 1901:

PERRY, T. B., passed assistant surgeon, granted leave of absence for 30 days from March 12. March 2.

BROWN, B. W., passed assistant surgeon, directed to report at Washington, D. C., for special temporary duty. March 5.

NYDEGGER, J. A., passed assistant surgeon, to assume temporary command of the Cape Charles Quarantine Station during the absence of Assistant Surgeon C. W. Wille. March 2.

CLARK, TALIAFERRO, assistant surgeon, granted 7 days' extension of sick leave from March 8. March 7.

TROTTER, F. E., assistant surgeon, relieved from duty as quarantine officer at the port of Cienfuegos, Cuba. March 1.

WILLE, C. W., assistant surgeon, granted leave of absence for 7 days from March 4. March 2.

BERRY, T. D., assistant surgeon, detailed as quarantine officer at the port of Cienfuegos, Cuba. March 1.

LONG, J. D., assistant surgeon, relieved from duty in the Hygienic Laboratory, Washington, D. C., and directed to proceed to New York, N. Y., and report to Surgeon L. L. Williams, Immigration Depot, for duty. March 5.

MACDOWELL, W. F., hospital steward, granted leave of absence for 30 days from March 20. February 26.

GOODMAN, F. S., hospital steward, relieved from duty at Havana, Cuba, and directed to proceed to Washington, D. C., and await orders. March 6.

NEWBERN, JR., WALTER, hospital steward, granted leave of absence for 30 days from March 5. February 27.

Foreign News and Notes

GREAT BRITAIN.

Physician Honored.—Sir James Reid, Bart., K.C.B., has been appointed a Knight Grand Cross of the Royal Victorian Order, in recognition of his services to her late Majesty.

British Congress on Tuberculosis.—Professor Robert Koch, of Berlin, Professor Brouardel, of Paris, and Professor McFadyean, of London, have promised to hold addresses at the Congress.

Decorations Conferred upon Nurses.—King Edward has conferred the decorations of the Royal Red Cross upon Miss Marian Lambert, of the Church of England Mission, Sister Jessie Molyneux Ransome, Miss Lillie Emma Saville, M.D., London Mission, and Miss Abbie Goodrich Chapin, in recognition of their services at the International Hospital during the siege of the legations at Peking.

Medical Appointments to the King of England.

—The following appointments are announced:
Honorary Physicians to the King.—Dugal McEwan, M.D.; Sir James J. L. Dennet, K.C.B., M.D., Inspector-General of Hospitals and Fleets; Sir John Watt Reid, K.C.B., M.D., LL.D., Director-General of the Medical Department of the Navy (retired); Adam B. Messer, M.D., Inspector-General of Hospitals and Fleets; Henry C. Woods, C.V.O., M.D., Inspector-General of Hospitals and Fleets (extra).

Honorary Surgeons to the King.—Sir James Jenkins, K.C.B., M.D., Inspector-General of Hospitals and Fleets; Timotheus J. Haran, Inspector-General of Hospitals and Fleets; Sir James N. Dick, K.C.B., Director-General of the Medical Department of the Navy (retired); William H. Lloyd, M.D., Inspector-General of Hospitals and Fleets; Alfred G. Delmege, M.V.O., M.D., Deputy Inspector-General of Hospitals and Fleets (extra).

CONTINENTAL EUROPE.

Influenza in Sweden.—The influenza epidemic is becoming more severe. Prince Bernadotte, second son of King Oscar, is among the sufferers.

Virchow Collection Destroyed.—Fire recently broke out in the Pathological Institute at Berlin, during which the remarkable Virchow collection was entirely destroyed.

Anti-tuberculosis Society.—A society for the prevention of tuberculosis in the Baltic provinces of Russia has recently been founded. Professor Dehio is president, and the headquarters of the society are at Dorpat.

Italian Pediatric Congress.—The subjects selected for discussion at the Italian Pediatric Congress, to be held at Florence from October 15th to 20th, 1901, are: Infantile Atrophy (Athrepsia), to be introduced by Professor Fede, of Naples, and Professor G. Berti, of Bologna; the Respiratory System of Early Infancy, by Professor C. Mya, of Florence, and Professor Mensi, of Turin; and the Acute Affections of the Digestive Apparatus in Sucklings, by Professor Concetti, of Rome, and Professor R. Guaita, of Milan.

German Surgical Congress.—The German Surgical Society will hold its thirteenth congress in Berlin from April 10 to 13. Among the general addresses are the following: Renal Surgery in the Nineteenth Century—a Retrospect and a Prospect, by Professor Kuster, of Marburg; Castration in Tuberculosis of the Testis, by Professor von Bruns, of Tübingen; A Report on the Second Series of a Thousand Excisions of Goiter; On the Operation for Struma Intrathoracica; and on the Treatment of Goiter Without Operation, by Professor Th. Kocher, of Berne; The Wounds Caused by Modern Firearms, by Dr. Schjerning, of Berlin; The Various Methods of Anesthesia and their Indications, by Professors von Mikulicz, of Breslau, and Bier, of Greifswald; Pneumonia after Laparotomy, by Professor Henle, of Breslau; The Indications for Extirpation of the Uterus by the Vaginal and Abdominal Routes, by Drs. M. Jordan, of Heidelberg, and Schuchardt, of Stettin; The Building Up of Carcinoma, by Dr. W. Petersen, of Heidelberg; Cancer Parasites, by Professor Nils Sjöbring, of Lund; The Surgical Treatment of Appendicitis, by Dr. Rehn, of Frankfurt-on-the-Main; and the After-Treatment of War Invalids and Victims of Accident in Watering Places, by Dr. Ziemssen, of Wiesbaden.

The Imperial Council of Hygiene.—The regulations for the new Reichsgesundheitsrath (Imperial Council of Hygiene) have been published by the Federal Council. The Council has been instituted in conformity with the new laws relative to epidemic diseases to be a consulting body in connection with the Imperial Health Office. The members are elected by the Federal Council, and the president and vice-president are appointed by the Imperial Chancellor. The membership is an honorary office and is tenable for only 5 years, after which time fresh elections will take place. The Imperial authorities and also the authorities of the individual confederated States have the right to send representatives to the meetings. The Council is authorized to send commissioners to make inquiries in any part of the Empire where intervention in hygienic matters seems to be necessary. There will be nine special committees of the Council, the functions of which will be to take cognizance of the following subjects: (1) Public health, including hygiene of dwellings, ventilation, etc.; (2) hygiene of food; (3) water supply; (4) hygiene of factories; (5) epidemic diseases; (6) hygiene of hospitals; (7) the pharmacopeia; (8) hygiene of shipping; and (9) veterinary hygiene. The "plenum" of the Council will meet only when convoked by the Imperial Secretary of State for the Interior. The proceedings are not public. It remains to be seen whether this program will be realized and how often the Imperial Government will think it requisite to convoke the Council. Care must be taken to prevent the Council from coming into collision with the medical departments of the individual States, which are very anxious to maintain their prerogatives in this respect, and whose influence is the greater, as the executive is entirely under their control, whilst the Imperial Council of Health is only a consulting body, without executive functions. Of the members of the Council the following prominent names may be mentioned: Professor von Bergmann, honorary F.R.C.S. Eng., the well-known professor of surgery in Berlin University; Professor Binz, of Bonn; Professor Buchner, of Munich; Professor Flügge, of Breslau; Professor Fränkel, of Halle; Professor Gaffky, of Giessen; Professor Gerhardt, of Berlin; Professor Robert Koch, the bacteriologist; Professor Löffler, of Greifswald; Professor van Noorden, of Frankfurt; Professor Rubner, of Berlin; Professor von Ziemssen, of Munich; and many others.—[*London Lancet*]

MISCELLANY.

Acetic Acid.—Acetic acid is now made in Germany from the refuse material obtained from the sauerkraut factories. The enormously increased production will reduce the price of the acid to a merely nominal sum.

Appointments.—**BASLE:** Dr. Karl Haegler, Privat-docent of Surgery, and Dr. Friedrich Egger, Privat-docent of Medicine, have been appointed extraordinary professors. —**COPENHAGEN:** Dr. J. Fibiger has been appointed to the chair of pathological anatomy in succession to the late Dr. Lange. —**KIEL:** Dr. Theodor Kirchoff, Privat-docent of psychiatry, has been granted the title of professor. —**LEIPZIG:** A new dermatological clinic has been opened; it is replete with apparatus for Röntgen rays for urethroscopy, cysto-

scopy, and the Finsen light treatment, and it is under the charge of Professor G. Riehl. —**KIEW:** Professor A. Murato of Dorpat, professor of obstetrics and gynecology. —**VIENNA:** Dr. Anton Freiherr v. Eiselsberg, ordinary professor of the University of Königsberg, has been appointed ordinary professor of surgery and head of the first surgical clinic in the University of Vienna.

Plague in Cape Town.—Bubonic plague is developing to a considerable extent in Cape Town. Fifteen new cases and 97 old ones were officially reported on March 11. The disease is extending to the better classes. Several persons have died from the plague on the streets of Cape Town. It is reported that the German Government has established a plague quarantine against vessels coming from Cape Town.

Obituary.—**DR. THEODORE HUSEMANN**, professor of pharmacology, aged 68 years, at Göttingen. —**DR. WILHELM ZÖLLER**, aged 75, at Heidelberg. —**DR. HERMAN PFLEFFER**, of Darmstadt. —**DR. SAN CRISTOBAL**, rector of and formerly professor in the medical faculty of the University of Santiago, Chili. —**DR. IGNACIO QUINTINO DE AVELLER**, surgeon to the Hospital de S. Jose, of Lisbon, aged 82 years. —**DR. HEINRICH SCHAPIRO**, professor in the Grand Duchess Helena Pawlowna Clinical Institute, St. Petersburg, aged 48 years. —**DR. LEOPOLD WEISS**, extraordinary professor of ophthalmology in the University of Heidelberg, aged 51 years. —**DR. JULIUS HOMANN**, assistant in the Hygienic Institute of Kiel. —**WILLIAM POPE MEARS, M.A., M.D., M.R.C.S.**, in Edinburgh, on February 22, aged 46 years. —**MR. BAEON ALFRED RICE, M.R.C.S., L.R.C.P.**, at London. —**MR. HENRY WILLIAM SCRATCHLEY, M.R.C.S., L.R.C.P.**, at Poole, on February 6, aged 38 years. —**PROFESSOR VICTOR PASCHUTIN**, Chief of the Military Medical Academy of St. Petersburg, aged 56 years.

Postmortem Vitality of Bacteria.—In a recent number of a German journal, devoted to bacteriology, an interesting summary is presented of certain results attained by Dr. Klein in the course of a long series of experiments made lately in which Dr. Klein endeavored successfully to ascertain what becomes of disease germs after the death of their victim. These experiments had a very decided practical value, as the conditions which they proved to exist dispose effectually of one of the arguments which has been often used by advocates of cremation.

These latter have held that disease germs could retain their vitality for an indefinitely long period in the buried body, and that, therefore, cemeteries, in addition to being harmful because of the decaying organic matter which they contained, were positively dangerous because they acted as immense storage reservoirs for the bacteria of the different diseases.

Dr. Klein's results correct this mistaken idea. In order to carry out his experiments satisfactorily he buried animals which had died from certain known diseases, disinterred the bodies at the end of varying periods, and examined the organs for bacteria.

The bacillus of Asiatic cholera was still living at the end of 19 days, but after being buried for 28 no living specimen could be found. The typhoid fever bacillus was able to exist for about the same length of time, while the germ which causes the bubonic plague was able to survive an interment of 17 days, but was never found living at the end of 8 weeks.

The bacillus of tuberculosis lives but a short time after the death of its victim. Dr. Klein always found it without difficulty in the organs, but was never able to obtain a successful culture. What is perhaps of even greater importance he was never able to cause tuberculosis by injecting the bacteria thus found into the system of a healthy animal.—[*New York Herald*]

Treatment of Senile Pruritus.—Jaenicke (*Centralblatt f. innere Med.*, Dec. 1, 1900) finds that in this condition the skin showed a peculiar dryness, was ill-nourished, and shiny. He concludes that the condition might be due chiefly to a collection of ill-nourished superficial epithelium, and treated one case by actively rubbing the surface with a soft brush in order to remove the superficial epithelium. This was repeated three times a day, being carried out for from 10 to 20 minutes. The results in this case and in others were extremely good. [D.L.E.]

1.—The report of the anesthetics committee of the British Medical Association is based on 25,920 cases, and includes the records of the administration of 43 distinct anesthetics, mixtures, or successions of anesthetics. But the administrations in over 21,000 cases were confined to chloroform, ether, gas and ether, A. C. E. mixture, and mixtures of chloroform and ether in various proportions. The complications under chloroform, and mixtures of chloroform and ether were more frequently of a dangerous character. Cases of danger were divided into two classes; those that recovered, 153; and those that died, 29. Under ether, gas and ether, and A. C. E., the proportion of complicated cases classed as cases of danger was, especially under ether alone, very far below the proportion of cases so classified under chloroform and mixtures of chloroform and ether. In 1,176 cases of the ether group, there was an average of 1 case of danger, due entirely to the anesthetic, whilst in the same number of cases of the chloroform group there were at least 6 cases of danger caused solely by the anesthetic. Probably the chief lesson taught by the report is that chloroform alone, or in combination, caused in the reported cases a danger-rate sixfold higher than the danger-rate produced by ether. The tendency for cases of complications and danger to arise was rather greater in the winter than during the rest of the year, especially under ether. This latter fact may possibly be due to the circumstance that bronchitis is far more prevalent after ether than after chloroform, and that bronchitis usually flourishes when the thermometer is low. The percentage of complications under all anesthetics together was greater in males than in females, whilst the percentage of danger cases was still higher in males than in females. The age period, from 11 to 15 years, had the lowest complication rates and danger rates under all anesthetics taken together; from this age onward there was a steady rise for each decennial period until the age of 50 in the complication-rate, and 80 in the danger-rate. Under chloroform the percentage of danger cases in the first 10 years of age was distinctly higher than in the second and third decennial periods. Of the 18 chloroform deaths, 3 were considered to have been due entirely to the anesthetic and 4 to the anesthetic principally, and the patient's condition secondarily. In the others, the patient's condition and the operation were held to be more or less contributory factors to the fatal termination. Of the 6 ether deaths not one was considered to be due entirely to the anesthetic. No method of administration of chloroform is free from danger, but an examination of the complicated cases appears to show that the occurrence of danger depends largely upon the administrator. In conditions of good health, chloroform is very much more dangerous than other anesthetics. In grave con-

ditions, chloroform still remains the least safe anesthetic, but the disparity between it and other anesthetics is far less marked than in health. Vomiting during anesthesia, which may lead to danger, seems to be more frequent under chloroform than under other anesthetics. The tendency for circulatory complications to appear increases directly with the relative amount of chloroform in the anesthetic employed. While vomiting is more common after administration of ether, severe and prolonged vomiting is more common when chloroform has been used. Circulatory depression following the administration of anesthetics is more common after chloroform than after ether. While the respiratory complications of anesthesia, as a whole, are of equal frequency in the ether and the chloroform groups respectively, yet those that occur under ether are mostly of a trifling and transitory nature, while those that occur under chloroform are more grave and persistent. After-vomiting is more common with ether than with other anesthetics, but it is usually transient. Bronchitis is much more common as an after-effect of ether than of chloroform. [J.M.S.]

2.—The article is a criticism of the report of the work of the anesthetics committee. [J.M.S.]

3.—Funk believes that vaccinia is not a microbic disease and that the etiologic cause of vaccinia is a protozoon, which he names sporidium vaccinale. In certain specimens of vaccine virus he took advantage of the large size of the cysts filled with spores to fish the latter out with a platinum wire onto discs of agar, and to make them into an emulsion with a sterile liquid. If under these conditions the author succeeded in reproducing the disease, it could no longer be doubted that he really had found the protozoon sought for. The spores were made into an emulsion with a drop of bouillon, and a calf was inoculated. About the sixth day, when the experiment was properly conducted, the characteristic pustules were observed. When calves are inoculated with fresh emulsions of the protozoon they are found to have become refractory to subsequent inoculations with vaccine. He also found that the variolous pustule contains a protozoon similar to the sporidium vaccinale, and concludes that the etiologic agent of vaccinia is identical with that of variola. [J.M.S.]

4.—Copeman attempted to cultivate the microorganisms of vaccinia and variola by employing collodion capsules, which, after being filled with beef broth and inoculated with a trace of glycerinated vaccine lymph, free from extraneous microorganisms, were sealed up and placed within the peritoneal cavities of rabbits and dogs. In successful cases the fluid contained no leukocytes, but it could be demonstrated, by the presence of an appreciable amount of serum albumin, that body lymph had managed to dialyze through the walls of the capsule. On making film preparations of the contents of an unruptured capsule, and examining them microscopically after staining with methylene-blue, in addition to flakes of epithelium numerous zoogla masses were visible, made up of bodies resembling spores, only the periphery of which took the stain. Apparently they represent the resting stage of the specific microorganism. The fluid contents of these capsules was, however, found to be capable of producing a typical eruption of vaccinia in the calf, although the contents of control capsules placed in test-tubes partially filled with beef broth and incubated at the body temperature for periods varying from a week to a fortnight gave no results. Dr. Fremlin and the author have recently demonstrated the presence of what appear to be similar microorganisms, often in extraordinary numbers, in the epithelium of vesicles in vaccinia of the calf and also in human smallpox. [J.M.S.]

5.—Will be treated editorially.

6.—All the cases of typhoid fever do not give the serum reaction, and the agglutinating property may not present itself until late in the disease; again it may be present at one period of the disease and absent at another. Horton-Smith estimates that it is absent in about 3% of all cases. The finding of the Klebs Löffler bacillus is of value in cases presenting doubtful clinical symptoms, but is of less importance when symptoms of disease are absent, or when the exact nature of the organism is doubtful. Failure to find the specific bacillus is only of value when confirmed by repeated examinations. In the case of blood-examinations failure to detect microorganisms cannot be accepted as proof of their absence, for the quantity of material examined is relatively

small. The chances of error with a positive result are, however, small and depend solely on the care and attention bestowed upon the sterilization of the syringe and skin. **Error in bacteriologic diagnosis** is frequently due to the fact that cultures only are taken and no films prepared. For example, an abscess is incised and some of the pus inoculated on culture tubes; no growth results, and the pus is regarded as having been sterile, whilst in reality it has been caused by an organism that does not grow on ordinary media, or that only grows under anaerobic conditions. Whenever possible, therefore, films should be prepared and stab cultures made in glucose medium. From neglect of these precautions, Symes has more than once failed to elucidate the cause of lesions that were probably due to such organisms as the *B. tuberculosis* and *B. capsulatus aerogenes*. Some organisms, too, such as the *diplococcus* of Fränkel, are far easier to recognize in fresh films than in cultures. [J.M.S.]

7.—Waggett describes an instrument for the protection of the observers in cases of infectious sore throat. [J.M.S.]

8.—Phillips reports two cases of typhoid fever, with abscess of the lung and empyema. [J.M.S.]

9.—The chief use of the phenylhydrazin-test for sugar is a confirmation or otherwise of the presence of sugar in urines, of which the total reducing power is equivalent to 5 parts per 1,000 or less. Before proceeding, however, to apply confirmatory tests the presence or absence of albumin should be ascertained. If more than a cloud is observed the coagulated proteid should be filtered off and Fehling's test again applied. This is essential, as Eastes has occasionally met with proteid-containing urines that react with Fehling's solution, the reaction not occurring after the separation of the proteid by heat and filtration. Should the reduction still take place we can then proceed with the phenylhydrazin test. Take of the filtered urine about 60 ccm. in a beaker of 100 ccm. capacity. Add 1 gram of sodic acetate and rather less of the phenylhydrazin hydrochlorate. Stir with a glass rod, which remains in the beaker throughout the entire operation. The beaker is then placed on a water bath and the urine gradually evaporated down to from 10 to 15 ccm. During this process the beaker should be occasionally removed, and any sediment collected on the sides of the vessel scraped off with the glass rod into the fluid. In this way none of the sugar is left by evaporation on the sides of the beaker. When reduced to the bulk above indicated the flame should be removed and the beaker, remaining on the bath, should be allowed to cool. This will take 2 hours or longer. When quite cold stir up all the sediment and with a pipette place some on a glass slide for microscopic examination. Ozonized crystals will have formed if there is one part per 1,000 or more of sugar in the urine. If no crystals are found it may be safely concluded that sugar (that is glucose) is absent. [J.M.S.]

10.—Hall describes a series of experiments to determine the exact times and quantities necessary to produce good crystals, and at the same time be sufficiently sensitive. From these it appears that 0.5 gram (7 to 8 grs.) of phenylhydrazin, 1.5 gram (22 grs.) of sodium acetate, and 5 ccm. (2 drams) of urine give the most rapid and satisfactory results with glucose, but that 10 ccm. should be taken if the solution contains maltose or lactose. Before adding the urine, the reagents should be dissolved by gently warming in a few cubic centimeters of water. When the urine is added the mixture is brought to the boiling point, and there maintained for fully 3 minutes with strong, and 5 minutes with weak solutions. The test tube need not be placed in cold water; it should be simply placed at rest. Within 2 to 10 minutes the crystals will be formed. [J.M.S.]

1.—Bennett describes a condition of quiet effusion into the knee-joint occurring in women and young girls. Although the effusion is greater on one side than on the other it is usually bilateral. Unless the part is injured there is very little pain. Excepting for a sense of weakness the patient is unaware of the existence of the swelling. The condition is limited to girls and women and is always associated with menstrual irregularity or uterine trouble, hence it is most common at puberty and at the climacteric. When the patient is standing the fluid occupies the lower part of the knee-joint and produces oftentimes a pouch like swelling at the lower and anterior part of the joint. Sometimes a slight injury will call attention to the existence of the effusion, and hence a diagnosis of traumatic synovitis is frequently made. Bennett reports a number of cases to illustrate his remarks. During the past four years he has seen 20 typical examples of this condition. It is practically never seen in other than the knee joints. No case recovered until the menstrual or uterine trouble had been corrected, but when this had been accomplished absorption of the fluid took place. Bennett bases a diagnosis on the presence of a painless effusion into both knee joints occurring in women associated with menstrual irregularity or uterine trouble, in which traumatism and other causes may be excluded. [J.H.G.]

2.—Bland-Sutton in his third lecture on *The surgery of pregnancy and labor complicated with tumors* takes up the subject of cancer of the neck of the uterus, tumors of the pelvis, misplaced viscera, and sequestered and quick extrauterine fetuses. He regards cancer of the neck of the uterus as the most appalling of all the complications of pregnancy. It is difficult to understand how a woman with this disease can conceive, but it is quite certain that it happens, and even when the disease is well advanced. He believes that cases in which uterine cancer offers obstruction to delivery are rare, and this for two reasons, namely: cancer of the neck of the uterus predisposes to abortion, and when it has advanced to such a stage as to occupy the vagina with an obstructive mass the effect of it upon the patient is such as endangers and often kills the fetus. It occasionally happens that even when the child is dead cancer may induce such changes at the neck of the womb as to render surgical interference indispensable. When pregnancy goes to term in such cases, cesarean section is the proper procedure to adopt. Tumors of the pelvis must be considered among the rare obstructions to labor. The ovoid shape of the tumors and their elliptical outlines are characteristic of all tumors which mould themselves in the true pelvis. Usually such tumors are chondromatous in nature. Dislocated kidneys and postrectal dermoids are occasionally encountered in advanced pregnancy or in labor at term. They may, and usually do, necessitate cesarean section. An enlarged and movable spleen is one of the rarest complications of pregnancy. It is a well-established fact that uterine and tubal pregnancy may run concurrently and both go to term. This may be described as the most dangerous combination to which child-bearing women are liable. In dealing with the question of concurrent, intra- and extrauterine gestation the cases require consideration in three categories: 1. Cases in which uterine pregnancy supervenes on a quiescent (sequestered) extrauterine fetus and goes to full term. In these circumstances it may end happily and even be successfully repeated. 2. An extrauterine and a uterine pregnancy begin simultaneously, but the complication is recognized in the early months and terminated by surgical intervention. 3. Uterine and extrauterine pregnancy running concurrently to term. All the recorded examples of this extremely rare combination have, with one exception, ended in disaster to the mother. [W.A.N.D.]

3.—Morison, discussing the diagnosis of appendicitis

with pus, urges the necessity of localizing, as far as possible, the exact position of the abscess, as the treatment to be instituted, as well as the prognosis, will depend upon the situation of the pus. In the diagnosis of pelvic cases of appendicitis, especially in women, difficulty is often met with, and the rectal and vaginal examination of such cases is strongly urged. When a diagnosis of pelvic abscess due to appendicitis has been made, Morison thinks that it is safer to drain such through the rectum in men, and through the vagina in women. When it is possible to do so in cases operated upon intraperitoneally, he thinks that not only the abscess should be drained, but the appendix should be removed in every case. When the abscess is found adherent to the parietal peritoneum, he prefers to open the abdomen above the abscess, to wall it off with gauze, and then open the abscess. In ligating the appendix and suturing it, he uses catgut. Drainage is always obtained through the posterior angle of the wound. Morison gives the mortality of appendicular abscess as 8% in the cases operated upon. [J.H.G.]

4.—Bannatyne, in an article entitled *Points in the classification and diagnosis of some joint affections*, states that no two men seem to agree as to the diagnosis of certain classes of disease. The author suggests the following classification: "(1) The bacterial or toxic arthropathies; (2) the nerve arthropathies and (3) the senile degenerative arthropathies." He divides all cases into two essential groups: (1) Those in which the principal symptom of the disease is the joint trouble, and (2) accidental arthropathies, the joint trouble not being the essential feature of the disease. In the first group may be included rheumatism, rheumatoid arthritis, gout, senile arthritis and pulmonary osteoarthropathy. In the second class he mentions the arthritis accidental to gonorrhea, scarlet fever, malaria and certain nervous diseases. He believes that microorganisms act as causes in nearly all forms of arthritis. From our present knowledge, the following classification is suggested: "(1) Bacterial or toxic arthropathies; (a) bacterial rheumatism, rheumatoid arthritis, gonorrheal and scarlatinal arthritis (and probably malarial arthritis); and (b) toxic, gout and pulmonary osteoarthropathy; (2) nerve degenerative arthropathies, such as occur in tabes, ataxic paraplegia, etc.; (3) senile degenerative arthropathies, such as senile arthritis." Attention is directed to 4 separate kinds of swellings or nodules which occur in various structures. Muscular rheumatism is regarded as a manifestation of the rheumatic poison. In this affection indurated patches in certain muscles are frequently observed; these areas represent interstitial changes in the muscle. In rheumatism, rheumatoid gout, etc., fibrous masses are not infrequently observed in the subcutaneous tissues. The subcutaneous masses have also been found in gonorrheal arthritis and malarial fever; the third variety of nodules consists of bursal swellings in connection with joint affections and occurs most frequently in chronic gout and chronic rheumatism; sometimes in rheumatism. Occasionally these swellings apparently have no relation to the joint. The fourth variety of swellings consists of osseous nodes, principally at the end of the phalangeal bones; these nodules occur in chronic rheumatoid arthritis and gout. Reference is made to the researches of Dr. Poynton and Dr. Paine, who have isolated a diplococcus from the joint fluids and joint-structures, in cases of rheumatism. Inoculation of this organism into animals gave rise to arthritis and other joint manifestations, as well as the other symptoms. The diplococcus was again found in the inflammatory lesions of the animal. The author believes that rheumatism is due to a specific bacterium. Two varieties of rheumatoid arthritis are mentioned; one being acute and the other chronic. Children and comparatively young adults are susceptible to the acute form; females being more frequently attacked than males, and the disease often follows such disorders as influenza, rheumatism, or tonsillitis. The clinical manifestations of the acute variety are swelling of the joints and an increase in the temperature. The joint becomes soft, or is distended with synovial fluid and bony formations do not appear. Vasomotor disturbances may develop in the neighborhood of the joint; pain in the varying grades of severity may be present and glandular enlargements are seen in the neighborhood of the involved joints. The chronic variety may follow the acute or develop insidiously. The joints gradually become crip-

pled, show great deformity, become enlarged and bony out-growths develop. The affection may spread to many joints, thereby causing pain, stiffness and deformity; in some cases even dislocation occurs. He mentions that von Dungern and Schneider have isolated a microorganism from the joints in cases of rheumatoid arthritis. When this bacterium was injected into animals the disease was reproduced and the microorganism was found in the joints. Dr. A. S. Wolmann and the author have isolated a specific bacterium. In the acute variety of rheumatoid arthritis muscular atrophy, which occurs in relation to muscles or certain groups of muscles, and increase in the tendon reflexes, have been observed. In the chronic form, the muscular atrophy was due to disuse, and tendon reflexes were not exaggerated. He believes that the joint manifestations of rheumatoid arthritis are not preceded by nerve troubles but arise secondarily; therefore, muscular atrophy seems to develop through reflex impulses. From a diagnostic standpoint, gonorrheal arthritis presents the following points of interest: The affection is always preceded by a gonorrheal attack elsewhere, most frequently in the urethra; the gonococcus produces the lesions in the joints and can be found in these structures. The severity of the primary attack has no relationship to the severity of the joint troubles. The joints of the lower extremities, particularly the knee-joints, are most frequently involved; great swelling without redness is the common character of the lesion, and cardiac complication is rare in gonorrheal arthritis. The diagnosis as a rule is easy when the gonorrheal discharge has been discovered, but it should be remembered that a vaginal discharge in women may be misinterpreted, and that gonorrhea may accompany gout; and it should not be mistaken for rheumatism. The salicylates, when administered, as a rule, point out the true nature of the affection. The arthritis, which is occasionally associated with scarlet fever, develops with the disappearance of the rash. The joints of the knee and elbows are most often involved in this affection and the disease rapidly subsides with the administration of salicylates. Arthritis, which occasionally develops with malaria, may have its origin either as true rheumatism, probably developing with the malarial affection, or it may be of malarial origin. He states that a point of interest is, that the occurrence of a gouty attack may cause one of ague; and further, that the administration of quinin in some cases of malaria seems to provoke a gouty paroxysm. The diagnosis of pulmonary osteoarthropathy may be attended with some difficulty, owing to its rarity and also because it may be confounded with akromegaly. In pulmonary osteoarthropathy the finger ends are clubbed and the carpal and metacarpal bones are thickened, and the disease is associated with such pulmonary affections as phthisis, chronic bronchitis and empyema. The author believes that the theory of a toxic condition of the blood or tissues seems to be the most likely solution of the determining agent in gout. The diagnosis of chronic gout from subacute and chronic rheumatism often presents difficulty. The joint involvement in gout is rarely symmetrical and is more liable to affect the joints of the lower limbs than those of the upper. The disease is more common in males, especially in the well-to-do, and often there are in association, digestive disturbances and irritability of temper. Little difficulty attends the diagnosis of arthritis which is due to tabes or other similar nervous affections. The arthritis of the senile is essentially a monarticular disease, especially affecting men and frequently following some injury; swelling is slight and redness does not occur. The author concludes the article by saying that arthritic troubles may develop from bacterial poison; from bacteria themselves acting upon the joint structures; from toxic poison, and from nerve degenerations and senile changes. [F.J.K.]

5.—Bunch delivered a lecture on "*Protective Inoculation and Serumtherapy*," before the North London Medical Society, on February 14, 1901. Reference is made to congenital immunity against scarlet fever, measles, and syphilis in animals; also that dogs are not susceptible to tuberculosis, and that fowls, rats, and pigeons are not susceptible to anthrax. He further states that field mice are susceptible to tuberculosis, while white mice are immune to this disease. Congenital immunity occasionally exists in some individuals as they may pass through epidemics of measles, scarlet fever, or smallpox, without contracting these diseases. It is also shown in the case of the negro, who

is not so liable to malaria. Attention is directed to the fact that immunity may be abolished or lessened in certain animals; for example, Charrin and Roger have shown that rats may lose their immunity to anthrax by exposing the animals to prolonged work, and thereby causing fatigue. Acquired immunity is brought about by passing through an attack of a disease, or experimentally by the inoculation of weak cultures which protect against more virulent cultures. Acquired immunity develops after smallpox, scarlet fever, and measles. Diphtheria, pneumonia, and gonorrhea, on the contrary, do not render an individual immune to subsequent attacks of these diseases. The various theories of immunity are considered. That of Pasteur and Klebs who believed that immunity to particular microorganisms is brought about because certain substances necessary for their growth were used up in the infected individual, thereby preventing a subsequent attack of a disease. Chauveau and Wernich hold that microorganisms produce certain substances which hinder the subsequent growth of these organisms. In this way the theory explains that diseases are brought to an end and subsequent attacks prevented. Buchner and Wolffberg believe that in certain infectious diseases, destruction of the weaker cell elements took place, the stronger cells being able to resist the invasion of the specific microorganism. Mention is made of Metschnikoff's phagocytic theory; also the researches of Nuttall, who demonstrated that certain fluids in the serous cavities of dogs have the property of killing anthrax bacilli. The blood-serum of white rats rendered immune to anthrax was shown by Behring to have lost the property of allowing anthrax bacilli to thrive unless large numbers are inoculated. Attention is also called to Ehrlich, who believes that antitoxins act by combining with toxins, similar to the chemical combinations of acids and alkalies. The author mentions that of late the phagocytic theory has been somewhat modified in that the leukocytes are believed to secrete a bactericidal substance which may inhibit the growth or destroy bacteria. The experiments of Buchner strongly support this view. In discussing the practical side of this question, the author mentions that artificial inoculation was probably practised thousands of years ago by the Chinese. Reference is made to the discovery of the protective action of cow-pox against smallpox, by Jenner, in 1798. This method has stamped out smallpox in many communities. Vaccination against swine fever by attenuated virus has stamped out this disease in some localities. In a similar manner anthrax vaccination has also been practised during the last three years with considerable success. Attention is also directed to the treatment of rabies. Injection of products elaborated during the growth of microorganisms has been attempted with the hope of curing certain diseases; tuberculin is given as an example; the treatment of tuberculosis with tuberculin has not, however, met with success. Recently protective inoculation has been tried with enteric fever. The method of Wright and Netley is mentioned. The observers use a culture of the bacillus typhosus which is rendered sterile by heating to a temperature of 60° C. and then adding a small amount of lysol to the sterilized broth-culture. The clear fluid is decanted and this is used for injections. The dose for an adult is 2 ccm.; a second injection is given as a rule, the dose being doubled. The symptoms following the injection of this fluid are frontal headache, shooting pains, rigors and syncope; at the site of the inoculation a certain amount of inflammation develops and some fever follows the inoculation. The inoculation cannot be considered satisfactory unless the agglutination test is positive afterwards. The author gives the statistics of Wright. Out of 11,295 individuals, one-quarter were inoculated against enteric fever; only 0.95% of the inoculated developed enteric fever and the death-rate among these was 0.92%. Amongst the uninoculated 2.05% developed typhoid fever; the mortality in this group was 0.31%. Reference is also made to 718 soldiers, out of which number 539 were inoculated; amongst the uninoculated 6.14% developed enteric fever, while amongst the inoculated ones the disease developed in 0.55%; the death-rate amongst the uninoculated was 3.35% against 0.27 of those who were subjected to protective inoculation. Mention is made of the researches of Behring and Kitasato on diphtheria immunity, and the statistics of Sidney Martin and Hunt are given, who have shown that the death-rate of diphtheria has been reduced from 28% to 17%. The author

states that the antitoxic serum treatment of plague has been followed with success by Calmette and other observers. The death rate at Oporto amongst 142 patients treated with an plague serum was 15%; 65 was the mortality percentage those not treated with the serum. [F.J.K.]

6.—Parsons remarks that there are certain well-recognized causes for metrorrhagia, such as fibromyoma, polypus retained products of conception, diseased appendages, or cancer. In this paper he discusses another class of cases which he says is not very uncommon, but about which very little is said in the text-books, namely, metrorrhagia, for which there is no obvious cause. Even when patients are examined under an anesthetic the surgeon fails to find anything wrong in the pelvis, and when the uterus is dilated there is nothing apparent to account for so prominent a symptom. Under these conditions the indication is to use the curet. In certain numbers of cases very little thickening of the endometrium is found, and then the metrorrhagia will often persist and perhaps be worse after the curetting than before. In such cases Parsons has been able to stop the hemorrhage permanently by the use of the constant current, and he advocates this method of treatment in preference to the risk of mutilation involved by hysterectomy. In those cases which are benefited by curetting the microscope shows the endometrium to be considerably thickened by an excessive glandular proliferation. The condition corresponds to that described by Wyder, of Berlin, as "interstitial endometritis." There is one other cause of menorrhagia to which Parsons refers, namely, retroversion of the uterus. The first indication here is to replace the uterus and keep it in its proper position. [W.A.N.D.]

7.—Durham and Myers have discovered a small bacillus in the organs of 14 yellow fever cadavers. The bacillus was found in the spleen, kidney, mesenteric, portal, and axillary lymphatic glands; also in great numbers in the lower intestine. Other microorganisms were not found in the organs. It is probable that Sternberg and other observers have not recognized this bacillus because it takes up stains with difficulty, and because it is also with difficulty cultivated on artificial culture media. Successful staining was accomplished with carbolic fuchsin solution diluted with 5% phenol solution. The bacilli stained after the solution had been applied for from 12 to 18 hours. Pure cultures were obtained in broth by inoculating this media with mesenteric glands the growth developed under a strict hydrogen atmosphere. The authors believe that the evidence in favor of this small bacillus, as being of etiological significance in yellow fever, is stronger than any that has been presented for any of the so-called yellow fever germs. [F.J.K.]

New York Medical Journal.

March 9, 1901. [Vol. lxxiii, No. 10]

1. Blood in the Urine as a Symptom, and the Diagnosis of its Source. JOSEPH WIENER, JR.
2. The Specific Treatment of Acute Dysentery. WILLIAM J. CRUIKSHANK.
3. The Pathology of Intrauterine Death. NEIL MACPHATTER.
4. Ichthyol in Treatment of Deep-seated Inflammations. WALTER T. SLEVIN.
5. Resorcin as a Preservative for Suprarenal Extract Solution. SEYMOUR OPPENHEIMER.
6. The Radical Treatment of Malignant Disease of the Larynx. ERNEST WAGGETT.
7. The Surgery of the Tubal Bodies, with a New Method of Operating. J. E. BOYLAN.

1.—Joseph Wiener, Jr., contributes an article upon blood in the urine as a symptom, and the diagnosis of its source. All cases of hematuria present a double problem for solution. First, the location of the bleeding point in the urinary tract, and, second, the cause. The family history frequently lends us valuable aid. For instance, in showing the tendency to tuberculosis or to the uric acid diathesis. The frequency and duration of the attacks should be determined. In renal hematuria the blood often appears suddenly and just as suddenly disappears. In cases of movable kidney and renal stone the hemorrhage follows a similar course. Long-standing attacks tend to exclude malignant disease. The effects of exercise, or rest, in the course of a

attack should be ascertained. In tuberculosis of the bladder here is a sudden appearance of bright blood which is not influenced by rest, while the hemorrhage due to calculi in the prostate bladder or kidney is generally more or less relieved by rest. A persistent hemorrhage, especially if it is more profuse at night, suggests tuberculosis, sarcoma or carcinoma. The author furnishes valuable tables of differential diagnosis between vesical tuberculosis and calculus. Also between primary renal tuberculosis and renal calculus. A table is also supplied giving the principal points of difference between the diagnoses of hemorrhage from the prostate, stone in the bladder, tuberculosis of the bladder, tumor of the bladder, stone in the kidney, tuberculous kidney and tumor of the kidney. An excellent bibliography is appended. [T.L.C.]

2.—Will be abstracted when concluded.

3.—To be abstracted when concluded.

4.—Walter D. Slevin recommends the following formula for the relief of superficial, as well as deep-seated inflammations. It consists of ichthyol, 45 grains; lead iodid, 45 grains; ammonium chlorid, 10 grains; petroleum, enough to make 1 ounce. It should be applied by rubbing upon the inflamed parts. The author has found the formula to be most effective when used in chronic conditions, inflammation, glandular enlargements, and ulceration, whether of specific nature or otherwise. [T.L.C.]

5.—Seymour Oppenheimer recommends a 1% solution of resorcin in sterile water as a preservative for suprarenal extract. The desiccated gland is added in the proportion of 60 grains to the ounce. [T.L.C.]

6.—Waggett discusses at great length the comparative merits of total laryngectomy and the operation of thyroectomy. He very much opposes the total removal of the larynx in cases of beginning malignant disease, as recommended by J. N. Mackenzie. He thinks that the less severe operation of thyroectomy is much to be preferred in these cases. Tables of statistics are given to show that both the death-rate and cures are better in this operation. He does not deny the use of the total extirpation in cases of far advanced cancer. He thinks that improvement in the treatment of malignant disease of the larynx will come with advancement in diagnosis, and the early institution of surgical treatment by opening the larynx and removing the diseased area. [J.H.G.]

7.—Boylan thinks that the best method of treating hypertrophy of the turbinals is by removing them by means of a cold wire snare or scissors or with a saw, rather than by the use of the cautery. In using the cautery more tissue is injured than that which is removed. He prefers a thin stiff wire and with this the tissues cut smoothly and with ease. [J.H.G.]

Medical Record.

1. The Period of Incubation of Yellow Fever. A Study from Unpublished Observations. HENRY R. CARTER
2. A Contribution to the Bottini Operation for the Radical Relief of Prostatic Obstruction. L. BOLTON BANGS
3. Acute Gastric Ulceration. H. NEWTON HEINEMAN.
4. Treatment of Acute Serofibrinous Pleurisy. CHARLES E. NAMMACK.

1.—Henry R. Carter, of the U. S. Marine-Hospital Service, contributes a valuable paper upon the period of incubation of yellow fever. In a study of 80 cases he has found that the shortest period of incubation recorded is 3 days; the longest 8½ days, while very few of the cases show over 6 days. Great pains has been taken to eliminate all sources of error in these deductions and they seem to be entirely trustworthy. [T.L.C.]

2.—Bangs in discussing the radical relief of prostatic obstruction relates his experience with the Bottini operation. He thinks the operation should always be regarded as a serious one and careful preparation should precede it. He thinks the operation can best be done with general anesthesia. Among the symptoms which follow the operation frequent urination is invariable. Hematuria is not infrequent, but usually subsides within two or three days. Particles of

burned tissue may be expected to appear in the urine after the first week. Fever is more or less frequent after the operation. Epididymitis occurs in a small number of cases. Bangs thinks that the post operative period is more nearly three than two weeks and emphasizes the fact that the after-treatment of these cases is as important as the operation itself. The patient should not be allowed to pass from observation until the urine is clear and all symptoms of irritation have passed, and if possible the bladder should be explored with the cystoscope. Among the complications which follow the operation incontinence of urine must be mentioned. It occurred in two cases out of Bangs' 86. Sixty per cent. of his cases have discontinued the use of the catheter; 20% have an increased amount of spontaneous urination and are able to reduce the use of the catheter from one half to only that which is required for occasional treatment; 20% received no benefit, or if any, but very little. The largest percentage of cures was among the patients wholly dependent upon the catheter. The time for voluntary urination to appear after operation varies. In some it occurred immediately following the operation, and the longest period was two months after operation. [J.H.G.]

3.—H. N. Heineman discusses the subject of acute gastric ulceration, basing the term upon the description of Dieulafoy to distinguish it from the well known gastric ulcer. Even when an arteriole only is involved, the hemorrhage may become serious. The great source of danger arises from the fact that the arteriole is eroded only to a small extent of its circumference, thus keeping it patulous and preventing retraction within the sheath of the vessel or formation of clot which would arrest hemorrhage. The arteries involved in 23 cases were the coronary gastric arteries in 6, and the splenic in 17 cases. The lesion can be described only as an acute ulceration of the mucous membrane, or of this, and the muscularis mucosae, unaccompanied by any bacterial invasion, and without other recognizable lesions of the walls of the stomach. The seat of the ulceration involves an area ranging in size of a pea to nearly ½ of an inch. It is most often found near the cardiac end in the grand cul-de-sac or the anterior wall near the greater curvature. As to etiology, gastric hyperacidity has been ascribed as the cause. It is regarded by others as an early stage of the chronic ulcer. Usually the sudden and excessive hemorrhage is the first sign. Exceptional nausea and gastric pain, vertigo, and syncope immediately precede and accompany the hemorrhage, the patient being previously in good health. Sometimes gastric pain, accompanied by nausea and vomiting, precedes the hemorrhage, while a slight elevation of temperature may also occur. As to treatment, the patient should be placed at absolute rest, and rectal alimentation resorted to for 3 or 4 weeks. An ice bag may be applied to the stomach, while nothing, not even water, should be given by the mouth. Intravenous or subcutaneous injection of serum should be used. Dieulafoy recommends 8 gm. of chloride of sodium and 10 cm. of nitrobenzoate of caffeine added to one litre of distilled water. The indications for operation are rather difficult to determine. If a patient has lost a half to one litre of blood upon several occasions within 24 hours, he is certainly in danger if not operated upon. The amount of blood lost is our best indication, but all clinical signs and symptoms should be considered. The author appends a valuable list of all surgical interventions for gastric hemorrhages bearing upon the condition described, and for chronic ulcer. [T.L.C.]

4.—Charles E. Nammack discusses the treatment of acute serofibrinous pleurisy with especial reference for the indications of tapping. He recommends this procedure, first, when life is directly threatened by asphyxia from compression or by cardiac weakness; second, when fluid has risen to the third interspace in front; third, in all lesser effusions when spontaneous absorption is unduly delayed. His medical treatment includes the local application of guaiacol, or of iodine when the effect of guaiacol on the heat-regulating and vasomotor centers is too pronounced. Internally he gives sulphate of magnesium in concentrated solution in sufficient doses to produce mild catharsis. It is important that the ingested liquids should be kept at as low a point as possible, and the consumption of as much table salt as the patient can be induced to take is recommended. Nammack states that in his experience progress is more rapid in those cases which are not tapped. [T.L.C.]

1.—Knopf in his article advises the early isolation of persons suffering from consumption in sanatoriums not only for the cure of the disease, but also to school them in the hygienic measures that actual experience gives in taking care of expectoration, how to protect themselves from reinfection, and what to do to get well and remain well. He also objects to institutions in which there are large numbers of these patients, and advises that a number of smaller sanatoriums would be better whether in the city or country. He also agrees with some authorities that there should be hospitals in the city used for the isolation of these cases and their treatment, and only the sanatoria situated at a distance should receive the incipient and more hopeful cases. [T.M.T.]

2.—Bierhoff calls attention to a peculiar change which is noted in bladder-walls under cystoscopic examination, which he regards as **intravesical evidences of perivesical inflammatory processes**. These changes are invariably confined to limited portions of the bladder wall, and occur in patients who present absolutely no obstruction to, nor difficulty in, urination. In the majority of cases, however, the patients, who were all women, had at some previous period suffered from parametritis or allied conditions. In a total number of 443 cases examined, in 214 a history of such an affection preceding the bladder-change could be obtained. In cases of perivesical inflammation of recent origin the bladder-wall will be seen to bulge inward over the side of the exudate. When the process is an old one and the exudate has gone on to organization, the cystoscopic picture is an entirely different one. The most characteristic appearance in these cases is the presence over parts of the bladder-wall of sharp scar-like formations, which arise to a greater or less extent above the surrounding wall, have a yellowish-white color, and tend to fimbriate at the end. The parts usually affected are the lower lateral and the upper posterior and postero-lateral portions of the bladder. These structures Bierhoff terms "pericystitic strands." Treatment of the recent processes usually results in the disappearance of the vesical changes. In the older cases the full resorption of the strands is yet undecided. [W.A.N.D.]

4.—Shaw states that the **tonometer** is by far the simplest and most satisfactory instrument yet devised for the estimation of the blood-pressure and describes it as follows: It consists of a pneumatic ring, mercury manometer, rubber ball and rubber tubing. The ring is made of metal and large enough to slip easily over and cover one of the phalanges. There is a hole in one side where the rubber tube is attached. The inside of the ring is covered with a thin rubber membrane and is air-tight, the only place that air can enter or escape being through the opening in the side. The manometer is simply a glass tube with a bulb filled with quicksilver. A scale is attached which registers up to 260 mm. The tubing is T-shaped with the ring, manometer and rubber ball attached on the free ends. These parts are separable, but by the use of leather washers the joints are made air-tight. Pressure on the ball forces the air into the mercury bulb and pneumatic ring, raising the mercury in the one end and distending the membrane in the other. To slowly regulate the pressure on the ball there is a small wooden press with a thumbscrew in which the ball is placed. The technic is simple. The pneumatic ring is slipped over the second phalanx of one of the fingers and the blood removed from the finger-tip by rolling a small rubber band down to the joint. The rubber ball is then compressed until the pressure exerted upon the digital arteries by the ring is greater than that of the blood in the arteries. The rubber band is withdrawn and the finger-tip should remain anemic. The pressure on the ball is slowly and evenly diminished until the finger-tip becomes intensely red. The height of the mercury in the tube is then recorded. [T.M.T.]

5.—Miller gives the following advantages and disadvantages of **subarachnoidean injection of cocaine** over general anesthesia: (a) that it has no effect on respiratory cardiac and renal organs; (b) that there is no danger from pneumonia in an old person after his prolonged etherization; (c) that there is no nausea or vomiting, inducing secondary hemorrhage in abdominal sections, brain or neck operation; (d) that the patient can overcome in a great measure by careful preparation of the patient and by an intelligent technic; (e) that the patient can confer with the surgeon during operation, if a modification of the original method is necessary. The disadvantages are: (a) uncontrollable headache, lasting sometimes a week; (b) nausea; (c) vomiting; (d) vertigo; (e) cyanosis; (f) elevation of temperature; (g) weakness; (h) relaxation of the sphincters, sometimes lasting seven days; (i) during operation patient may become restless. The drug must be sterilized and Keen's dose is 15 minims of a 2% solution of eucaine. [T.M.T.]

1.—Edes reports the case of a single woman, aged 48 years who had enjoyed good health up to June, 1898. Her appetite and digestion had been excellent, and repeated inquiries failed to disclose anything like attacks of gallstones. The patient had been in the country riding a bicycle and enjoying herself. One day she came home saying she was very tired and was going to bed. Within a day or two there was a loss of appetite, intense jaundice, and light-colored stools. Neither then nor at any other time was there any severe pain or tenderness on pressure. This condition lasted essentially unchanged until her death. During the course of the disease, which was more than a year, there was some swelling of the legs, which, however, later disappeared. Ascites was also present for which she was tapped 18 times about 12 or 14 quarts being drawn at each operation. At the autopsy, the gallbladder was found to be enlarged and to contain many cholesterol gallstones. The biliary passages were enormously dilated within the liver, and the hepatic duct and the common bile duct were also dilated to a point 2 inches from the duodenum, where there was an abrupt narrowing. At the point of narrowing there was a small rounded tumor, which proved to be an enlarged lymph-node. There was a very small **carcinoma of the papilla at the orifice of the common bile-duct**. A rapid, complete nonfebrile jaundice in a person over 40 or 45 years of age, preceded or accompanied by no severe and painful paroxysms and succeeded by a moderate amount of diffuse pain and tenderness, especially after it has lasted long enough to exclude catarrhal jaundice, is an adequate basis for a highly probable diagnosis of carcinoma of the bile-duct. If, late in the smooth nonnodular edge of the liver, with the gallbladder tense but not tender, presents below the ribs, it is also highly probable that the lesion of the ducts was primary. Unfortunately, the presence of painful paroxysms is not so decisive in one direction as their complete absence is in the other, for even if significant of gallstones, this does not exclude carcinoma. A distinction between a growth originating in the walls of the duct itself and a small malignant or other tumor in the head of the pancreas pressing upon it, and producing total occlusion there before giving rise to symptoms elsewhere, would certainly be very difficult to make. The important point is to determine as early as possible the exact location of the growth, and this cannot be done without an operation. [J.M.S.]

2.—In the city of Boston, in the management of **diphtheria cases**, 2 consecutive negative cultures for release from quarantine are required instead of one. Furthermore, each of the 2 consecutive negative cultures for release

must be taken from both the nose and the throat of the convalescent patient. The Board of Health does not take the position that a sick person is necessarily suffering from diphtheria simply because a positive culture has been obtained, although this is usually true. The board does insist, however, that such a person is a nucleus from which the bacilli may be spread, and remains such until the bacilli disappear. The board recognizes that the patient may be harmless, despite the positive culture, if the bacilli in his nose or throat are not actively producing toxins. But since the methods for determining that the bacilli fail to produce toxins are impossible of application in practice to large numbers of cases, the board feels justified in assuming that they are virulent on the strength of much evidence that shows that the error involved in the assumption is small. Hence it is, that a positive report on a case for diagnosis is considered sufficient evidence for the isolation of the sick person as infective. While a positive report indicates clearly the presence of diphtheria bacilli, a negative report is by no means such good evidence of their absence, particularly in laryngeal cases. A no growth report is used when for any technical reason the examination of the culture is a failure. The principle of release by culture in diphtheria is analogous to that of waiting for the desquamation to cease before release in scarlet fever. Release on one negative culture allows 30% of the total positive persons released to go out of isolation while the bacilli are still present. Extensive investigation has shown that if two consecutive negative cultures for release be demanded only 1% to 3% of those released will be still infective. [J.M.S.]

3.—Swasey reports the case of a boy, 16 years of age, who sustained a large, ragged wound, involving the left eye, eyebrow, and part of the frontal bones, the result of a gunshot explosion. The eye was enucleated and it was then found that the superior orbital plate was pushed down, and nearly filled the orbit. The breech-pin and screw were impacted in the wound in the frontal bone, and when they were withdrawn they were followed by a good deal of soft brain matter and blood. For a time the patient did very well and then headache, pain in the back of the neck, restlessness, convulsions, a state of stupor, and twitching of arm and leg developed. The left arm became paralyzed and the patient died. At the postmortem examination the whole frontal lobe of the cerebrum was found to be practically destroyed. The remaining portion of the brain appeared quite healthy, except that the left lateral ventricle contained pus and that there was evidence of a basilar meningitis. The author believes that the last two lesions were the sole cause of the fatal termination. [J.M.S.]

4.—A certain proportion of cases of convulsions in early childhood are but the beginning of true epilepsy. Bullard and Townsend conclude from a study of 7,180 case records: 1. That 1% of the children applying for treatment at the Boston Children's Hospital came for convulsions. 2. That 10% of children between 5 and 12 years of age gave a history of convulsions. 3. Cases that appear to be due to some manifest reflex cause may turn out to be true epilepsy. 4. Other cases in which the attacks occur frequently and without apparent cause, may suddenly recover, at least, for a considerable period. 5. That children who have had convulsions may be strong and free from nervous tendencies in later life, although the proportion who have nervous tendencies seems to be greater than in those that have not had convulsions. [J.M.S.]

2.—Tuttle gives an interesting and instructive account of operations done in the aged. He reports 131 operations done in patients over 60 years of age, with a mortality of three. Two of these deaths were caused by pneumonia due to unavoidable exposure after operation, and the third was due to Bright's disease. The majority of the operations might be classed as major, 30 being for inguinal hernia; the three deaths occurred in this class. Thirty-five operations were done for hemorrhoids. There were two cases of appendicitis and two of resections of the intestine, both of these latter patients being about 70 years of age, and in one patient 21 inches of the small intestine were removed. Ether was used 83 times, chloroform 13 times and cocaine 30 times. Tuttle does not think that a small amount of albumen in the urine should be taken as a contraindication to operation, but that patients with fatty and epithelial casts should be rejected for operations of election. Organic valvular diseases of the heart, unless of the most marked character, are not a bar to ordinary surgical procedures, but fatty heart and degeneration of the muscles are contraindications. Fat, flabby old people are not good subjects for operation. He thinks that the utmost celerity consistent with good work should be had in operations upon old people. Shock was very seldom seen in his cases. The patients in this series were in a county institution and were not selected cases. [J.H.G.]

3.—Van Zwalenburg reports a case of sarcoma of the intestine, occurring in a 5-year old boy, and apparently having its origin in a traumatism. He resected the entire ascending colon with 5 or 6 inches of the ileum. At the time of operation the patient was in a very bad condition, emaciated and very anemic and running some temperature. Six months after the operation the patient was perfectly well, and had gained 17 pounds. The growth was a small round-cell sarcoma. It was about the size of a hen's egg, and surrounded the ileocecal valve. There was another growth which was smaller and occupied the small intestine 4 or 5 inches from the cecum. Van Zwalenburg presents a table classifying 15 cases of sarcoma of the intestine in which resection was done, all of which have occurred since 1882. He concludes that sarcoma of the intestine is more common than is generally supposed, and that it more frequently affects the small than the large intestine, the ileum being the favorite location, and that stenosis is rare, but dilatation is more frequent. [J.H.G.]

4.—Mitchell outlines the rest treatment for hysteria. He advises this plan of treatment in all cases of hysteria, except when complicated with certain acute diseases, especially uterine and periuterine. The earlier the treatment is instituted the more favorable the results, and, as a rule, well-marked cases of hysteria receive the most benefit by this treatment. Mitchell prefers to send patients to a private house rather than to a hospital or sanitarium. Great care should be exercised in the selection of a nurse; she must have certain personal accomplishments, such as being able to read aloud, which are not a necessary part of a nurse's education. Isolation he regards as a most important measure in the treatment. Only the physician, the nurse, the masseur and the servant should see the patient. If the patient be in a private room of the hospital, the resident physician should only make one daily visit. Isolation must be continued from six to eight weeks in an ordinary case, but the calendar must not be the index which regulates the duration, as some cases may require a much longer rest. Absolute rest in bed should be instituted. The ordinary diet may be given, but at the beginning milk is the best article of food. Massage is advised once daily, preferably given by some other person than the nurse. Daily use of electricity is recommended, more because it fills an hour or so of the day, which helps to keep the patient occupied. He treats insomnia with the cold-dip, the wet-pack, or an abdominal compress. At times massage at night, or the application of electricity, induces sleep. The use of drugs must be avoided

as much as possible. He emphasizes that the after-care of the patient is of great importance, and he has made it a rule to follow such cases for about six months. [F.J.K.]

5.—F. Savary Pearce reports a contribution to the study of **hereditary subnormal color-perception**. The patient, a man, could not distinguish red from green. Excepting chronic cystitis following hypertrophy of the prostate gland, and arteriosclerosis, no organic lesions could be demonstrated. There was slight accentuation of the aortic second sound. There was hypochondriasis and recurrent melancholia. Ophthalmoscopic examination was negative. Visual fields were neither contracted nor reversed. There were no optical defects. The patient had first noticed the abnormal color-perception while performing his duties as a seaman. The family history showed that one of the children had chorea, one daughter was very nervous, and another suffered from lateral curvature. A daughter of 15 years of age was the only discoverable case of diminished appreciation of red and green in the family. The patient's mental condition had always been peculiar. A year after he was first seen by the author he became afflicted with delusions of insanity, and died eight months thereafter in an insane asylum. [M.R.D.]

6.—Drake suggests that the name **neuricity** be applied to the specific energy peculiar to nervous tissue. He believes that giving this form of energy a distinctive name emphasizes its importance, and that it will simplify the study of its action, and the formulation of its laws. [F.J.K.]

7.—Culbertson, in an article on **psychic therapeutics**, states that the treatment by suggestion should form a part of a reputable physician's armamentarium, just as certain books, instruments, medicines, and surgical appliances form a part. Personal influence, he believes, is so powerful and important a therapeutic agent that it cannot go unrecognized. [F.J.K.]

8.—Gleason discusses the various operations for the **correction of deflections of the nasal septum**. He thinks that septal resiliency does more to prevent success than any other one factor. He then describes an operation which he has found very successful in 6 cases of lateral deflection of the whole tip of the nose. [J.H.G.]

9.—Pyle reports a case of **extensive laceration of the external ocular muscles, diplopia, spontaneous recovery**, occurring in a physician, aged 44, in good general health. The injury occurred while the patient was riding a bicycle, and was due to the end of a blunt splicing hook of No. 10 telephone wire penetrating the conjunctiva of the right eye near the inner canthus, and making its exit toward the external canthus, the line of injury keeping below the cornea. The sclera was not perforated. The wound healed kindly under antiseptic treatment. Diplopia followed, which a local optician could not relieve by any prismatic correction. There was crossed diplopia, due to injury of the inferior rectus, and homonymous diplopia pointing to injury of the inferior oblique muscle. Fusion of the images and single binocular vision were obtained while the patient was sitting erect in a straight position facing a small circle of light at about the level of his eyes, slightly lowering the chin and rotating the latter to the right until the head was inclined to the left at an angle of about 75 degrees. Removal of the blinder from the right eye, which the patient had been wearing, partially relieved the diplopia. Repeated attempts at correction finally resulted in obtaining comfort for the patient by prismatic correction. [M.R.D.]

Wiener klinische Wochenschrift.

February 14, 1901. [14. Jahrg., No. 7.]

1. Transitory Absence of the Knee-jerk after Cerebral Injury. A. PICK.
2. The Mechanical Treatment of Certain Forms of Vertigo. V. URBANTSCHITSCH.
3. Iodipin as a Means of Diagnosis. FRANZ WERNER.

1.—Pick reports 4 cases in which the knee-jerk was absent for some time following an injury to the head. The first man was kicked in the face by a horse; in his case knee jerks were obtained only a week later, for the first time. The second man had been struck in the head

by a locomotive. In this case the knee-jerks were not found until 5 days later. The third case received a stab-wound in the right parietal bone, after which the left knee-jerk failed until death 6 months afterward, though left hemiplegia followed. In the fourth case, a man who had been shot in the mouth, both knee-jerks were absent for 12 days. Pick considers that the amount of shock is the probable cause of the failure to elicit knee-jerks for some days after cranial injury. [M.O.]

2.—Urbantschitsch reports the case of a man in whom, following operation for caries, with otitis media, the semi-circular canals were opened. His vertigo was so great that he could not even go upstairs. Hearing was unaffected. As the vertigo was no better 10 weeks after operation, Urbantschitsch started **rhythmic head exercises**. Methodic movements of the head were begun and kept up. Then they were increased in frequency until but a slight instability remained, which the patient did not notice himself. Urbantschitsch has tried this treatment with much success, in many cases of vertigo due to ear disease. [M.O.]

3.—In using **iodipin for diagnosis**, the preparation must not contain free iodine. It must therefore be kept away from light, air, or heat. While, ordinarily, the saliva will not react with iodipin, causing the formation of free iodine, this reaction does rarely occur, though only after a long time. Nor is iodipin absorbed by the mucous membrane of the esophagus during its passage into the stomach. The normal stomach secretions, being acid, do not break up iodipin. Therefore, when iodipin is employed medicinally, no alkali should be given. From the fact that iodipin reaches the pylorus intact, and is only later broken up and absorbed in the intestines, in the presence of bacteria and the secretions of the glands of the intestinal mucous membrane, by the fluids from the gallbladder and the pancreas, comes the possibility of the use of iodipin as a means of diagnosis in 6 distinct affections. It is used to ascertain the gastric motor activity, iodipin appearing in the saliva in 45 minutes at the most (an average of 27 minutes), when the stomach is normal. The cause of its appearing after 45 minutes, due to a sluggish action of the motor function of the stomach, is generally gastric catarrh, from congestion in heart disease, fever, gastroparesis, etc. Motor activity is normal when the heart affection has not caused congestion. Iodipin will be especially useful here, in cases in which the use of the stomach-tube is contraindicated. Secondly, in insufficiency or incontinence of the pylorus, from cancer or ulcer, iodine will appear in the saliva in from 10 to 20 minutes after iodipin has been taken. When the bile or pancreatic juice is absent from the duodenum from any cause, the time before the appearance of iodine in the saliva is directly proportionate to the amount of jaundice present. In cases of total closure of the common bile duct, iodine only appears several hours after the iodipin has been ingested. Fourthly, widespread inability of absorption in the intestinal mucous membrane or mesenteric lymph system, from atrophy, amyloid disease, tuberculosis, peritonitis, or enteritis, will also be shown by the length of time after which iodine appears in the saliva. On tapping, in ascites, the presence of iodine in the fluid withdrawn will make the diagnosis ascites chylosus. Besides, the failure of iodine in the saliva and urine, after taking iodipin, with other causes excluded, will point to closure of the thoracic duct. Finally, in chyluria, whether from parasites or not, iodipin given per os will cause the appearance of iodine-fat in the urine. Five tables sum up the statistics of the 102 cases used in these experiments. On account of its unpleasant taste, iodipin should be given in capsule, or with peppermint. The article is full of details, with many references cited. [M.O.]

Deutsche medicinische Wochenschrift.

6. Mastitis Adolescentium. R. ADLER.

2.—Schmidt reports a case of fatal scalding of the pharynx and larynx occurring in a child, 3 years of age, which had attempted to drink from the spout of a tea-kettle containing boiling water. A remarkable feature of the case was that immediately after the accident no local manifestations were present. During the night, however, there were evidences of dyspnea and dysphagia. Cutaneous emphysema next occurred, the dyspnea increased, requiring the performance of tracheotomy. The patient died on the following day from cardiac failure following a left-sided pneumonia, death occurring with high fever, accelerated pulse and coma. Postmortem examination confirmed the clinical diagnosis of pneumonia. The epiglottis was thickened and rigid. The mucous membrane on the laryngeal surface of the epiglottis as well as the mucous membrane of the larynx were necrotic as far as the false vocal cords. On a level with the endolaryngeal necrosis there was also found an area of necrosis at the point of transition between the pharynx and the esophagus. The ring of necrosis throughout showed an elevation of about 1 cm. The fact that the scalding was not followed by simultaneous pathological manifestations in the mouth and pharynx is explained as being due to the deep introduction of the spout of the kettle into the mouth, the bending backwards of the head in the attempt at suction and the entrance of the steam or the boiling water by reason of the deep inspiration caused in the attempt to scream. The frequency of tea-drinking in England has caused a number of these accidents and the author states that English literature on this subject shows an appalling amount of such cases. The complicating cutaneous emphysema is explained by the pathological findings in the larynx and the pharynx. In consequence of the necrosis of the mucous membrane at the transition from the pharynx to the esophagus the emphysema, analogous to similarly observed cases, may have originated from here as well as from the larynx. At all events, on account of the inflammatory swelling and constriction of the larynx, the resulting spasmodic, deep inspiration may have afforded the possibility for the entrance of air into the submucous tissue and still further through the interstitial tissue to the skin. [M.R.D.]

3.—Moritz has administered acetate of lead to rabbits, and after various doses has been able to produce basophile granulations in the red blood-cells. He also found that of 6 workers in a lead factory all showed typical granulations, and only one had any suspicion of intoxication. One had previously had lead poisoning. He considers that these granulations are of marked diagnostic value in the diagnosis of lead intoxication. He has also seen them in leukemia, malaria, sepsis, and the cachexia of carcinoma. [D.L.E.]

4.—Fokker states that more colonies develop from sour milk than one would expect from the number of bacilli visible upon microscopic examination, and the number of bacilli present is much larger when the sour milk is filtered hot; he considers therefore that there is some albuminous substance which has a vicarious action. This is very similar to casein. If heated to 22° or higher it coagulates, and produces soluble granules in alkaline fluids. The bacilli continue to increase on the second day, and since existing bacilli cannot reproduce by simple division, and since if the casein is filtered no further development occurs, he reaches the conclusion that the bacilli were developed from the casein. After the second day fermentative processes hinder the development of the bacilli. [D.L.E.]

5.—Strebel gives an elaborate discussion of the Finsen therapy and his own method, together with a technical discussion of the best method of accomplishing results. [D.L.E.]

6.—Adler describes an affection of the mammary glands, attended by considerable pain, swelling of one or both glands, and the development of considerable sensitiveness to touch. The malady usually occurs at the time of puberty. The treatment consists of applying tincture of iodine, mercurial ointment, and a protective bandage, and, in very marked cases, extirpation of the gland. The author recommends that, when

extirpation has to be resorted to, the nipple be left intact for cosmetic purposes. [M.R.D.]

3. Concerning the Frequency of Sugar in the Urine of Obese Individuals. F. WOLFNER.
4. Mania with Depression. W. WEYGANDT.

1.—Will be abstracted when concluded.

2.—Karo describes two cases of rectal gonorrhea following the evacuation of gonorrheal pus into the rectum. The author concluded from the clinical course of his two cases that gonorrheal suppuration of the prostate gland may, upon spontaneous perforation into the rectum, give rise to rectal gonorrhea. This should be taken into consideration when an incision into such abscesses is contemplated. In one of the author's cases there was an acute spermato-cystitis which later also perforated into the rectum, causing rectal gonorrhea which, however, occurred without subjective difficulties.

3.—Wolfner examined the urine of 996 obese patients and found sugar present in 10% of them. He believes that the percentage of diabetics increases with the degree of obesity. [M.R.D.]

1. Insane or Criminal? E. RÉGIS.
2. General "Tics Convulsifs" Cured by Respiratory Gymnastics. A. PITRES.

1.—In this article Régis comments upon a communication by Coriveaud and Sebileau, who, after examining an individual accused of having attempted murder, concluded that he was an alcoholic, irresponsible at the time, from alcoholic delirium; that he had recovered when they saw him; and that he could be liberated. A few months later he had another acute attack, gravely injured three people (one of whom died), and attempted suicide. At this examination he was found irresponsible, and taken to an insane asylum. Régis thinks these experts were correct in all but one particular, that is, that the patient should be observed for a long time before being liberated, in order to be sure that he is cured. Even then a return of the delirium is probable. He says that most insane patients are liberated too soon nowadays from the private institutions. [M.O.]

2.—Pitres presented a case of general "tic," occurring in a man aged 20 years. There had been no nervous diseases in his ancestors, but he had had convulsions with unconsciousness up to 7 years of age. The convulsive movements began at 9 years, after a fright. They were present in the body and grew gradually worse. At 10 years he had some internal treatment, after which he improved, the amelioration lasting to his seventeenth year. Then the "tic" began again and grew worse. The movements existed in the head, body, and extremities, from 1 to 20 a minute. With each movement a shrill cry was associated. They ceased during sleep. Regular breathing, singing, reading aloud, and lying down diminish them. He could not be hypnotized. For a month, with his back to the wall, for 10 minutes thrice daily, he tried respiratory gymnastics, breathing deeply and slowly, elevating both arms at the same time. The movements gradually decreased and he left the hospital. Since then he has kept this exercise up and is now cured. Even his fear and love of solitude, which had been so noticeable before, have disappeared. [M.O.]

Rattlesnake Venom as a Cure for Leprosy.—A Brazilian physician claims to have cured several cases of leprosy with rattlesnake poison. Several cases of leprosy that were claimed to have been cured by rattlesnake bites led him to make these investigations.

STRANGULATED AND GANGRENOUS HERNIA. KELOTOMY AND LAPAROTOMY IN STRANGULATION, EXTERNAL AND INTERNAL; ARTIFICIAL ANUS—ENTEROSTOMY, PRIMARY OR SECONDARY RESECTION—ENTERECTOMY, AND END-TO-END OR LATERAL JOINTING IN GANGRENOUS HERNIA.*

By THOMAS H. MANLEY, PH.D., M.D.,

of New York.

DURING the past 20 years no single branch of surgical pathology has had so much attention bestowed upon it as visceral hernia of the reducible or incarcerated type.

Its etiology has engaged the attention of some of our most noted master-minds, as has also its clinical history, its course, treatment and termination. Almost numberless procedures have been devised for its operative cure.

It is somewhat remarkable, however, to note that while advance has been made in the therapy of reducible forms of hernia, but little if any departure is noted from antiquated methods in the treatment of that type of hernia that kills, the strangulated, in many modern textbooks and systems of surgery.

Radical revolutionary methods are adopted, very properly, by the profession, with great reserve, and the more ancient procedures, established and promulgated by eminent authority, are set aside with reluctance. We have not yet fully outlived that strange dread of the peritoneal membrane, nor, in strangulated hernia, can we forbear the vivid recollection of the harrowing mortality which so often followed kelotomy for its relief, in our student days. Of some 7 cases of kelotomy witnessed by myself in my own school and hospital courses, every one of them sank within 48 hours. So great, indeed, was the mortality from operative effort that every resource was exhausted before kelotomy was tried; hence the patient was often in mortal collapse before the scalpel was taken in hand. And though the patient realized the desperate chances he was taking, it is evident that the surgeon was also keenly alive to the trying ordeal before him, as Abernethy tells us that always before an operation for strangulated hernia, he felt like a man about to be hanged. The introduction of anesthetics seemed to make little impress on mortality, as the late Dr. Frank H. Hamilton, as recently as 1880, affirmed that the mortality from strangulation remained about the same as in the time of Hey; viz., 60 to 70%.

Practitioners yet held their patients back until surgery was nearly powerless to resuscitate dying individuals; the faulty, timid, imperfect methods in vogue in operating left a large number unrelieved, to die from adhesions of the coils, stricture, kinking, asphyxia, gangrene or perforation of the gut. In those days surgeons knew nothing of the technic of intestinal surgery, nor of aseptic methods; experimental surgery on modern lines was quite unknown, and, moreover, the echo of the warning of Peyronie, Richter and Duverger yet dinned in their ears; that "the deductions derived from animal experiments had no application on the human being."

PART I.

MORTALITY IN STRANGULATION AND SOME OF ITS CAUSES.

It strikes one as rather incomprehensible how so eminent a surgeon as the elder Gross should advise against early kelotomy, and that he should allege that operation was often premature and taxis would save more than the incision. The older authors regarded kelotomy, in a large measure, in the same light and submitted figures to prove it. Thus, Gosselin treated 53 cases by taxis and lost but two. He kelotomized 61 and lost 31.

At about this time Heusser, of Paris (1861-1865) recorded 227 cases operated, with 172 deaths, a mortality of 75.08%. Later, Tschering and McCready, in 1888, published statistics on this aspect of the subject; the former, 524 operated—29% mortality; the latter, cases collected from 1869-1888, operated—36% mortality. Hennegeler, in 1896, 296 kelotomies—23.02% mortality. Bochart, same year, 86 kelotomies 16 deaths—17.97% mortality. Hagedorn (1883-1890) 170 kelotomies—14% mortality.

The Causes of Fatal Changes in Strangulation of the Intestine.—Conditions which lead to grave or fatal symptoms in strangulation arise from numerous sources. Primarily, they are *anatomical*.

1. Enteroptosis, compression of the gut, with alimentary impediment, or asphyxia.
2. Torsion of the gut.
3. Stricture or partial stenosis.

The intestine, forced out of the abdominal cavity in slow stages, accommodates itself to its new abode; but when this occurs suddenly, as after a strain at stool or in making any violent effort, distressing symptoms may follow. Duplay and several other noted surgeons have insisted that a *torsion* or a twist in the coils of gut was one of the most prolific causes of strangulation; and it is noted in these cases, that the constriction at the neck of the sac is seldom great and that the circulation is not completely strangled. These are evidently the class in which the intestine preserves its vitality for several days after strangulation.

Direct stenosis with torsion of the coils or not, from constricting pressure at the neck, plays a wider role than any other anatomical factor.

The parts most actively concerned in nipping the bowel are all fibrous; but the aponeurotic structures above are all continuous with muscular elements, and are by them more or less influenced. Heretofore, but little attention has been bestowed on the consideration of the part which the intestine itself plays in the etiology of strangulation. The intestine is a muscular tube, highly vascular, with a thick mucous lining and serous investment. Its movements are serpentine and it will permit of more manipulation and abuse than any other organ, in a serous cavity. Its muscular energy is extraordinary, for an organ apparently so fragile and delicate. In many cases of strangulation, if not crushed and crippled by violent manipulation, it will tend to draw the coil which has slipped out, back into the abdomen; and when the grip is tight, it will yet maintain a tug on the trapped parts at the ring until it has totally freed itself from the herniated segment.

The small intestine is supplied by blood through the mesenteric ligament—a large, movable, loosely-organized structure, conveying numerous arteries and a great number of large veins. In all cases of strangulation the condition of the mesentery is a matter of dominant importance, as it is only when this is com-

* Read at the Pan-American Medical Congress, Havana, Cuba, February 4, 1901, before the Section on Gynecology.

promised by great or protracted pressure that the vitality of the intestine is threatened, and much depends on the state of the vessels in this structure at the time of operative reduction whether the gut is to perish or recover function.

Sex in Strangulation.—Berger, in the *Bureau Centrale*, of Paris, in the examination and record of 10,000 hernia cases in both sexes, found that strangulation occurred three times more frequently in the female than in the male; its symptoms were more grave, gangrene was more frequent, and its mortality was larger. Gibson observes that while women bear abdominal surgery with remarkable impunity, in resection for gangrenous hernia the mortality is larger than in men.

He collected 354 cases of gangrenous hernia operated between 1888 and 1898. One hundred and twenty died—34%. Males, 123; 34 deaths; mortality, 28%. Females, 209; 82 deaths; mortality, 39%. Dr. Gibson is inclined to believe that the anatomical difference in the structures of the female may account for the greater mortality, but this impression is lacking a rational confirmation, though clinically every surgeon well knows that every phase of strangulation in women is of a very grave character, and operative mortality has been very large. With women, the onset is more sudden and its progress towards death very often terribly rapid. This has been often verified in my own practice. In one case coming under my care, the woman, in the morning, while out in her garden, stooped to pick up a rake which had fallen from her hands. In an instant she was seized with all the symptoms of strangulation. In the evening of the same day she was sent to the hospital in a state of grave collapse.

Two hours after admission, while she was in a state of desperate exhaustion, she was operated under ether-anesthesia. But already the gut was the seat of gangrenous rupture and the sac filled with feces; before it was possible to divide the stricture and fix the broken-down bowel in the wound, she expired, 11 hours after the first symptoms.

Delay in Operating. Forcible and Protracted Taxis.—The statistics of Madelung and other investigators clearly demonstrate that the mortality after kelotomy is in direct proportion to the extent of delay in operating, and that sanguinous intervention offers little hope after symptoms of mortal collapse set in.

In former times when every description of peritoneal surgery was availed of only as a *dernier resort* this delay was perhaps justified, but at the present such a course is cruel, is indefensible, and places the responsible attendant *particeps criminis*, and reponsible in a great degree for the consequences. Some of the most harrowing examples of this have come to my own knowledge. In one instance the unfortunate woman was jostled into a cab *in extremis* and reached the hospital a corpse. In another, after three practitioners had exhausted themselves on the strangulated hernia of an old man, of ample means, he was hustled off in a driving snowstorm at midnight to a hospital, to sink, before hasty preparations for a kelotomy could be made. Another case was sent in, the patient, a middle-aged man, who suffered three days from strangulation with repeated and forcible taxis. When I saw him he was in profound morphin narcosis and moribund; but the hernia was reduced.

On autopsy the following day, it was found that a gangrenous gut had been ruptured and forced into the abdominal cavity, which was now flooded with feces.

Many other cases might be cited of a similar character. Certain it is that in some of this class of cases one is in a quandary to know what to do when operation is declined by the patient or family; but it should be plainly stated that at the proper time, in skilled hands its dangers are insignificant, and that protracted delay involves new risks and may remove all hope from any effort of relief. Protracted, or *maladroit* taxis probably more than any other cause augments the mortality in strangulation. Southam well observes that, "the high mortality in strangulated hernia is largely due to two causes: First, delay in operating, and, second, from the injury previously inflicted on the contents of the hernial sac by forcible, prolonged and repeated taxis." And yet, with our knowledge of the great harm inflicted by violent manipulation, it is curious to note that so distinguished an authority as Mr. Jonathan Hutchinson is still a champion of it; though, of course, since he is no longer an operator his views have little weight in this branch of surgery.

The Limitation of Taxis.—There are several eminent surgeons who go so far as to discount taxis altogether in strangulation. When there is no evidence of organic disease present and proper facilities are at hand for operating, in no case should taxis be employed in any stage of strangulation, but every time, there and then, the intestine should be liberated and the hernia radically cured by one of the many available methods. With patients averse to radical surgery, or other cogent reasons, judicious taxis alone, or combined with other resources, will often effect the reduction.

In nearly all cases sent to a hospital for operative relief, the most determined taxis has been employed, the extruded intestine has been crushed or lacerated, the mesentery has suffered in its nerve and vascular structures, the gut is crippled and palsied, reduced to a state bordering on gangrene if it is not already sphacelated in patches. On this head, a recent writer truly observes: "That in these modern days a strangulated hernia delayed for operation till, on an average, more than four days have elapsed, shows that there is still much missionary work to be done."

Incomplete or Antiquated Methods in Operation.—The mortality succeeding kelotomy for strangulated hernia in the past was greatly augmented by operating by methods which were established on mistaken, erroneous principles, or a lack of knowledge of the pathological changes. In the preanesthetic period we can well imagine the supreme importance of rapidity in operating; but since operating has become painless, and since wound-infection can be eliminated, it seems incomprehensible how any relic of an ancient kelotomy can yet survive; how anything can still justify the use of Cooper's herniatome, the blind incision, the unaccountable fear of hemorrhage, the leaving of a *closed* sac or the practice of pushing *en masse* the whole adherent or tangled, perchance devitalized intestinal loop back into the abdomen. No wonder, indeed, an enormous mortality is recorded.

The time has now arrived when the whole superstructure of surgical technic in operations for strangulated hernia must be remodelled, and one who operates here should be thoroughly trained in the art of intestinal surgery. Operations for simple, strangulated hernia, performed early and properly should have no mortality whatever; those late and complicated, in patients whose condition warrants it, should be followed by a mortality under 10%.

In every instance when symptoms point to complete stricture of the intestine, with systemic toxemia, the surgeon should have ample preparations made *before* he begins, to make an intestinal resection, a partial or complete enterorrhaphy, to laparotomize and freely explore the abdominal cavity. When we proceed to operate, Riedel advises that we must cast aside the herniotome and cut freely down on the constriction with a scalpel; and that no attempt at reduction should be made in gangrenous cases, until the intestine is freely exposed.

PART II.

MORBID ANATOMY AND PATHOLOGY.

In a general way it may be said that strangulation occurs in two varieties of ruptures; in those which were reducible and those which were irreducible before the accident; in the former, on exceptional occasions, in femoral hernia on its first appearance.

What is understood here as irreducible or incarcerated herniae are those not coercible to the truss or having adhesions.

Of strangulation we have essentially *two* types. One *primary*, or external, and *secondly*, the consecutive or internal, which *may follow* operative reduction, and which has so largely augmented mortality.

The primary dangers in hernial strangulation are from (a) a sudden interruption of a physiological process, a double occlusion of the alimentary canal, with fecal stagnation; (b) the interruption or arrest of the vascular supply to the trapped intestine; and (c) from gangrene or mortification of it.

The *temporary occlusion* of the alimentary current in a hernia is seldom productive of marked pathological changes, either local or general, except where the degree of constriction is so great as to induce violent reflex disturbances; something singularly common in female strangulation.

The contents of the intestine—it being quite invariably the ileum—in groin ruptures, are gases and liquids, sometimes pure blood. The impediment to the intestinal current, in itself, either through impeding digestion or inducing coprostasis, *per se*, cannot be regarded as a grave accident immediately imperilling life; the harm comes later, through the violent reflex disturbances; the reversing of the peristaltic wave, with agonizing distress and profound cardiac depression. But symptoms of grave omen are seldom in evidence until secondary changes have commenced in the hernia, which ultimately lead to partial or complete death of the intestine.

Pathological changes are accentuated through the mesenteric structures involved, through considerable and long-continued pressure on the bloodvessels, which lead:

1. To an intense engorgement of the walls of the intestine, very considerably increasing its volume.

2. By inflammation with large serous effusion into the sac or a fibro-plastic exudate firmly gluing the walls of the intestine together *above*, as well as below, the site of stenosis.

3. Unrelieved inflammation passes on into gangrenous changes; but we never find any considerable segment of intestine entirely mortified, though gangrenous processes are widespread. Here and there is thrombotic occlusion of an arterial radical in the mesentery; or those ramifications of it nearest to the convex surface

cease to convey blood, and mark the site of mortified patches.

The mucosum, the layer calling for the greatest vascular supply, is the first to part with its vitality, to erode and ulcerate, and, lying in immediate contact with decomposing ingesta, is a prolific source of infection, of inflammatory and gangrenous changes.

The free hemorrhage into the bowel before or after kelotomy, the uncontrollable diarrhea from ulceration, the stenotic contraction and subsequent stricture sometimes observed after herniotomies, usually result from a lesion of this delicate structure.

Lesions of the Mesentery and Intestinal Muscle.—The mesentery is the bond which unites the alimentary tube over its greatest length, conveying the blood and lymph vessels and nerves. It is a membranous structure made up of elastic fibrous tissue and smooth muscular elements. That it possesses contractile energy is apparent to anyone who has observed its movements in the living animal. In various pathological and traumatic conditions its tonicity is impaired or lost, when it permits of varying degrees of enteroposis or derangement in the movements of the intestine. Mr. Treves has called attention to the great role of the mesentery as an etiological factor in hernia; and again, we may observe here with advantage, the part a traumatized mesentery plays in some of those fatal cases recorded after kelotomy. A turgescient, edematous, pulseless mesentery, of a bronzed color and a granular or leathery feel, possesses but little if any functional activity. It is in very much the same state of vitality which we observe after the main arterial trunk of a limb has been suddenly occluded by a ligature or damaged by an injury. There is a very large and free anastomosis between the vessels of the mesentery, so that when one area of supply to the intestine does not exceed six or eight centimeters, the vitality of the segment cut off is supplied by the excess at either healthy end. When this fails, or reestablishment of the arterial current is too long delayed, the organ on the distal end is slowly, but surely, deprived of its vitality; it lies in the sac, or reduced in the abdominal cavity, as a foreign body.

In some types of strangulation the mesentery may suffer greater tension or compression than the intestine; so that on its return to the abdomen it is in a functionless, enfeebled state, permitting of a sagging, kinking or twisting of the bowel. It is, therefore, obvious that the mesentery deserves a critical consideration in aggravated varieties of strangulation; that the diseased part should be resected, that its elongation be obviated by tucking or imbricating its folds, and so adjusting it that its circulation may be unencumbered and it may promise the greatest support to the intestine.

The *intestinal muscle*, next to the mucosum, constitutes the most important anatomic physiological structure of the alimentary canal. If we examine under the microscope, a sagittal section of an injected specimen of gut, we will find that as the arteries split up in the submucosum numerous and large divisions pierce and ramify through the muscular fibers. In the full circulation of life we will find the muscularis about twice as thick as it is after death, when the arteries are emptied; and hence the reason that intestinal suturing is much easier on the living than the dead intestine in the human being. Physiologically the musculature of the intestine, its motor power, must be regarded as of vital importance in alimentation; in (a) in maintain-

ing the open lumen, (b) in moving on and reducing the ailment.

It is curious to note clinically, that inflammation involving its inner lining, the mucous membrane, accelerates its peristaltic activity, while peritonitis, or inflammation of its serosa, induces a diminution of peristalsis or entirely suppresses it. Traumatic muscular inertia, inflammation or gangrene of gut after section of the constriction and reduction, are those pathological conditions of a post-operative character which have so largely contributed to a fatal termination in strangulated hernia.

Paralyzed and powerless to contract, the damaged coil permits of no passage of the alimentary contents through it. Its now vitiated, pent-up contents, undergoing decomposition, set free infective bacteria, which readily penetrate the intestinal wall and invade the peritoneal cavity. In the greater number of cases, general invasion by infection is arrested by processes of nature, by the fibro-serous exudate of the peritoneum which seeks first to localize infection by adhesions, by a gluing and binding together of the condemned structures preparatory to their final destruction by suppurative or gangrenous processes.

In *external*, or primary strangulation nature's intervention may prolong life or even effect a cure; but in *secondary* or *internal*, after reduction, her efforts in this direction are practically abortive and in most cases only hasten the end. In all cases of recently acquired hernia there is no force so constant and effective in reduction of the extruded coil, as muscular retraction of the healthy, free ends within the abdomen. This is a potent influence in strangulated cases. Immediately on the nipping or occlusion of the intestine it is thrown into a state of tonic spasm with a great strain put on the neck of the imprisoned loop.

One case came under my care in the person of a young man, which again illustrated how this aid of nature may have disastrous consequences. A man of 24, was sent to the hospital by his family for the treatment of a strangulated hernia of 10 hours' duration. On entrance, a strangulated inguinal hernia was discovered. He begged not to be operated till the following day. No taxis was at any time employed. The following morning the hernia had disappeared, but he had all the signs of general peritonitis and sank two days later.

On autopsy, a perforated, gangrenous knuckle of the ileum was found, with large fecal leakage into the peritoneal cavity.

In one of my own cases of successful intestinal resection of gangrenous hernia, a 30-inch loop was spontaneously detached on one side, and nearly so on the other. Pressure, no doubt, was the main factor in effecting this spontaneous excision, but there can be no question that the severance was accelerated by intestinal retraction from above.

Tumultuous spasm or inflammation of the intestinal coils promptly induce what the French designate *peritonisme*, or muscular rigidity of the abdominal walls.

Rigidity or *simultaneous* clonic spasm of the smooth and striped muscle, therefore, comes into action as the first pathological phenomenon in actual cases of strangulation.

The Peritoneal Exudate.—The serous secretion of an aqueous consistence, from the peritoneum in health in various pathological states provoked by trauma, becomes of a glairy, gluey consistency and finally serves the purpose of a veritable cement or solder.

This gives rise to *adhesions*, that salutary provision of the economy for walling off the healthy from diseased tissue, but which so often in hernia involves troublesome complications, though plastic operations on the peritoneum, or intestinal jointing would be impossible without it; the rapid transmutation of this plastic exudate into solidly organized tissue, has no analogy in any other tissue of the body. The plasticity and effectiveness of the peritoneal secretion or exudate depends on a free circulation in the substratum of its endothelial layers, and hence the reason, that *below* the point of constriction in the sac of a strangulated rupture, although there is commonly a considerable quantity of serous effusion, there are rarely adhesions of the omentum and intestine or the coils themselves; though when pressure at the neck of the sac is not great or the stenosis of intestine is largely dependent on a torsion of the bowel in the upper segment of the sac, the hernial contents may be more or less glued together.

External and Internal Strangulation.—The fatal defect in the older operations for strangulation was largely dependent on the erroneous conclusion that *all* the danger attaching to this state emanated from the imprisoned intestine *outside* the abdomen, and that when the constriction was released and the protruding loop was pressed up inside the abdominal cavity, the resources of art were exhausted; when fatalities were set down as due to "shock or peritonitis."

In all cases of strangulation the primary, gross lesion is limited to the parts of the alimentary canal caught in the constriction and below it. But, when considerable delay is permitted, when there is torsion of the bowel and a large segment of the mesentery is carried down, having attachment to a portion of the gut above, this may suffer from the effects of ischemia equally with that projected outwards; therefore why so often symptoms of strangulation persisted after the ring of constriction had been freely divided, and an apparently healthy intestine had been reduced; coils of intestine above were matted together, were palsied and partly asphyxiated or on the verge of gangrenous perforation. But, unsurgical methods in the absence of better, in dealing with external strangulation, were the most fruitful source of the harrowing mortality after the antiquated kelotomy of the past; as now, at times; and what had been an *external* strangulation was soon converted into an *internal*, which became a grave post-operative lesion.

Simple external strangulation, dealt with promptly by skilled hands, has a low mortality, if any at all in healthy individuals. On the contrary, the *post-operative* or *internal* is a state of great gravity, quickly fatal very frequently in spite of all resources of modern surgery.

In *internal* or *post-operative* consecutive strangulation, when the element of collapse is absent, "toxine absorption or enteric paresis" are often makeshifts which will not explain its mortality. Delayed or incomplete surgical treatment in a larger measure than any other agency explains the former heavy death-rate in these cases resulting from incomplete reduction of the hernia, or the forcing up, into the abdomen of kinked, adherent, asphyxiated or gangrenous coils of intestine. Mr. Frederick Treves gives us a graphic and faithful description of some of these post-operative complications, in a recent contribution. After reduction, he says: "In the first place, the gut may lie in the abdomen *hors de combat*, so damaged that its coats are quite inert; it is an

irritant to the peritoneal nerves, it interrupts peristalsis and acts as an obstructing agent, as would a piece of rubber tubing introduced in the line of the living intestine. . . . Perhaps a laparotomy is performed and nothing is found to account for the persisting symptoms, and nothing abnormal save the listless dead or dying loop of intestine." He adds, that Mr. Potts records two cases in which, after reduction, he performed laparotomy for persisting symptoms and found no cause save that presented by the free but listless coils that had been treated too late.

From the testimony of this noted authority, as above stated, those lives were lost not only by delay, but also because a *crippled hernia*, an *asphyxiated*, a "dead or dying" *intestinal loop*, *supersaturated* with septic elements, was carried up into the abdomen, which should have been freely *resected*; and nothing but freely vascular and highly animated parts reduced. This would have obviated internal mortal strangulation.

Southam, in 1891, published the statistics in 85 cases keletomized for strangulated hernia. There were but 27 deaths. In 16 of these, *postmortem* examination was made. In 4 the bowel was found to be the seat of gangrene; in 10 ulceration and perforation had taken place at the site of constriction; 1 died of general peritonitis and one of diabetic coma. Here we find ample confirmation of the view taken of the most common cause of death after operation for the relief of strangulation; that it frequently results from preventable causes, viz., the return to the abdomen of infected, diseased segments of the intestine which at the time of operation should have been excluded or resected.

Incomplete Reduction and Atypical Anatomical Varieties.—Incomplete reduction may occur with a timid or inexperienced operator. Some years ago such a case was recorded by myself, in which I was called to see if anything could be done for a young man, dying 3 days after a kelotomy for strangulation. The case was reported in detail in the *New York Medical Record*, May, 1894.

On examination it was found that the unopened sac and contents were pushed up and fixed in the inguinal canal, the constriction not yet divided. Happily the opening of the sac under cocaine and free incision through the neck promptly relieved all symptoms.

Another case came under my notice on autopsy in which a middle-aged man died on the day following kelotomy. The operator, finding on exposure of the parts nothing save an apparently adherent epiplocele, divided the stenosis, leaving the omentum undisturbed. There was no amelioration in the symptoms, thence on to death. Freely exposing the part *post mortem*, a concealed gangrenous loop of intestine was found, just protruding through the ring and nearly divided by the tight constriction, undiscovered. This was another example of "shock and peritonitis." In the old days of blind cutting and hasty manipulation, similar cases were, no doubt, not uncommon.

Van Buren Knott has collected 66 cases of peritoneal and intestinal hernia. He observes that in all cases in which the tumor is of an unusual situation and form, incomplete reduction may occur, and, unless we observe special caution, we may assume reduction, yet strangulation remains. In all this class, we should operate, he says, whether they are strangulated or not. In this, certainly all surgeons are in full accord.

A *complete reduction* of a strangulated intestinal loop *always* presupposes a *complete liberation* of it from adhe-

sions. In a strangulated, old, large, incarcerated hernia both free liberation and reduction may be injudicious because of the menace to the vascular supply of the bowel in its new abode. But in all other than these exceptions, in old people, the freest possible liberation of the intestine is essential as a prerequisite to its reduction. Robaix and Duplay have at length described the complex character of these adhesions, so often formed in simple irreducible and strangulated hernia. Rather than risk the return of the volvulus, we should resect and joint.

In hernia *en bisac* we will often discover in old, chronic cases of the irreducible or incarcerated, that when they become strangulated they are a most complex and difficult class to deal with in a hurried operation. In one case of the femoral type coming under my care, the patient of Dr. John Gillespie, of this city, besides a small protrusion containing a short loop—a Richter hernia—there was an old, thick sac, nearly as large as a fetal head, containing the cecum and several loops of small intestine, not only deeply congested and bound together but also united firmly to the base and walls of the sac by organized adhesions and bridles of new tissue. In this case the ring was freely opened, all the adhesions removed and the wandering coils returned. Death followed on the third day, the symptoms of strangulation remaining unrelieved, the result of imperfect surgical methods. In the same season, the winter of 1893, a somewhat similar case of strangulation came under my care in the practice of Dr. John Plunkett, also of New York. The case was one of strangulation of a large, old exomphocele without a true peritoneal investment, in a woman of 60, in deep collapse. Here a free liberation of the adhesions at the ring was all that was ventured; a free drainage provided for the escape of peccant fluids and a loose dressing applied. Immediate relief of symptoms followed.

These two cases illustrate a large class of *adherent* hernia in strangulation, in which consecutive or post-operative symptoms of a grave character may be usually entirely obviated by *limiting our intervention to intestinal liberation* and in no manner disturbing widespread adhesions through which, now, the intestine derives its nutritive supply, in its new abode. However, in young subjects, invalided by their infirmity, a resection of the omentum and intestine is a justifiable means of cure.

PART III.

SYMPTOMATOLOGY.

One of the most prolific causes of dangerous changes in strangulated hernia is a tardy recognition of it; as there are no pathognomonic symptoms of this condition, and no features of a clinical character which distinguish internal enteric obstruction from stenosis of external constriction in strangulation; nay, more, acute gastric, hepatic or renal colic may simulate the agony of strangulation.

Dr. Gibson's tables on this subject include several desperate cases of strangulation in advanced pregnancy, wherein one certainly might be led to confound or mistake the hernial distress for labor-pains. Many a practitioner is, indeed, quite in the dark when he first sees one of these cases, until the patient calls his attention to a "sore lump" at the navel or groin.

I have seen an aged lady in the moribund state from

an unrelieved, strangulated umbilical hernia, who was supposed to be suffering from "gastritis."

In those advanced in years, and notably in females, there may be an absence of symptoms or they may be of a complex character. Mr. Carle, of Lyons, notes an interesting case of this kind in a man of 72 years, with no redoubtable symptoms, and yet, on exposure of the hernial tumor, a gangrenous patch of the cecum was found requiring resection, the size of a five-franc piece. A huge abscess had formed and from this a ball of feces as large as a hazelnut escaped. This indefinite symptomatology in strangulation also applies to its complications. Thus, in a recent case of gangrene of 19 inches of gut requiring resection, in my service at Harlem Hospital, the patient had no vomiting whatever. In another case seen by me in Dr. George V. Hahn's practice, in the aged father of a physician, the patient had *no pain*; but, recurring fecal vomiting led to a search for rupture, when a small inguinal hernia was found strangulated—Richter's. On division of the parts, a fecal abscess with a rotten intestine was found. In the greater number, acute constipation with violent colicky pains and vomiting lead us to suspect strangulation.

Diagnosis.—An early and accurate diagnosis is as important in strangulation as rational and definite therapy; and what leads up to this in a larger degree than any other aid, is a searching investigation into the history of the case and a careful examination of the abdominal portals. Hernial tumors are seldom painful, hence the patient deceives himself and others, not infrequently. For this reason, we must accept with reserve any statement of the patient not confirmed by a physical examination. Occasionally, we will encounter tumors in the groin, so similar to hernia that nothing less than an examination through an incision will reveal their true character. I have seen a young man who had a strangulated hernia which was opened by the scalpel under the mistaken impression that it was a bubo. This mistake cost the poor fellow his life. In another instance I was called to the hospital to operate for "acute internal obstruction" in a young woman. She was in deep collapse and everything was in readiness for a laparotomy when I arrived. A strangulated femoral hernia was easily made out; but she assured me she had the fulness from childhood and that a physician had informed her that it consisted of enlarged glands. A kelotomy under cocain saved her life.

Certainly, we may have inguinal adenitis or abscess with a strangulation, as we may also have neoplasmata—hydrocele, spermatocele, etc. In a case of a mixed character with complex symptoms, diagnosis should be definitely determined when urgent symptoms are present, by an exploratory incision.

In gangrenous strangulation with perforation of the intestine, lasting over several hours, there is certain to be diffuse cellulitis which may be accompanied with an extensive edema of the parts, purulent infiltration, and a pointing over the tumefaction with a gangrenous plaque of the integument on the point of giving way; in fact, the parts present all the common characters of a huge abscess. We can always readily differentiate here, if we take the precaution to carefully percuss the tumors, as invariably in gangrenous hernia we have an infiltrated loop of intestine which emits a tympanitic note.

In the femoral hernia of the female, with a large adipose development, the projecting knuckle of intes-

tine may be so small and so deep seated that it will elude detection in many cases, unless a most painstaking examination is made when the first symptoms of abdominal colic set in. In those advanced in years, devoid of acute sensation, any sudden, violent disturbance of digestion attended with colic should lead us to suspect strangulation.

Treatment of Strangulation; Palliative and Radical.—

In simple, reducible, congenital or acquired hernia the natural tendency in nearly all types is towards spontaneous return to the abdomen, or with but moderate mechanical aid. The same holds true in a considerable number of cases of strangulated. A loop of intestine is suddenly thrust out of the abdomen and tightly caught by parts acted on by muscles. The whole intestinal canal is immediately thrown into violent, tumultuous contractions with convulsive agony and great depression of the vital powers, the whole physical equilibrium has sustained a violent shock. Now, if the patient be placed on a comfortable couch and given a small dose of morphine hypodermically and left severely quiet, with free warmth to the body until immediate agitation passes off—say, for from two to six hours—in all other than exceptional cases moderate taxis will effect reduction in a large number; many will reduce themselves. But immediate, repeated and forcible taxis is disastrous in a large number and frequently fails. I have seen a case that resisted violent and repeated taxis, which was sent to the hospital for operation, and which, after a small opiate and a few hours rest disappeared of itself, and again others after anesthesia return with the greatest ease, on taxis. Some, surely enough, had disappeared to the chagrin of the operator before they were brought to the table. The relief of intestinal and muscular spasm should, therefore, be our *primary* aim; then, after reaction has set in, we may try taxis if operation is refused. Some cases of strangulation, however, are quickly mortal if not operated without any delay whatever, and even then they may not rally from shock and sink. An example of this lethal type I recently saw in a young man seized with strangulation on the sidewalk on his way from dinner. His agony was so great that he had to sit on a step until an ambulance was called. He was operated the same day at 5 o'clock and died before midnight. Deepening shock and fecal vomiting call for *immediate* operation. Local application of ether or ice on the seat of the strangulation are expedients of doubtful efficacy. They are supposed to overcome spasm and subdue inflammatory changes, but they depress the circulation and endanger the vitality of the intestine; they are really makeshifts of the incompetent. Inversion of the body, large clysters and violent force applied over the hernia are brutal and barbarous measures, the relics of ancient surgery which cannot now be permitted under any circumstances whatever.

Our responsibility with this accident is always great, and hence, in order to proceed with that course the most advantageous to our patient, we should resort to those expedients which have been well proven to be the safest as a general rule. And here, we must turn to operative surgery early or not at all. No reputable surgeon should attempt operation on the moribund sent in, in his dying moments, by the practitioner. He should simply do his duty and leave the case in the coroner's hands.

Kelotomy and Laparotomy.—The modern operation for strangulation is essentially a new creation, based on

scientific knowledge and extraordinary advances, especially in the art of intestinal surgery. It aims not only at *relieving the constriction*, but also at *repairing the damaged intestine* and permanently curing the hernia.

Preparation of the Patient.—The room chosen to operate in should be thoroughly cleansed, well lighted and warmed. Besides the anæsthetizer, the operator needs at least two capable assistants. It is needless to say that the most scrupulous antisepsis must be employed and every possible complication provided for before the first incision is made.

In exceptional, unusual cases, attended with profound collapse, wherein we venture only to quickly relieve the constriction, cocaine analgesia can be substituted for pulmonary anesthetics, greatly to the advantage of the patient, or we may cocaine up to the division of the stricture and then continue with pulmonary anesthesia.

It is important to remember that in most cases, immediately on liberation of the intestine the most alarming symptoms pass off. Dr. Lewis (*Columbus Medical Journal*, 1884, p. 156) records an illustrative example of this in a case of inguinal strangulation. The patient, he says, "was delirious, wearing the expression of great pain and anxiety so commonly noted in advanced cases; all of which disappeared on opening the sac and dividing the ring."

Inasmuch, however, as troublesome complications accompany the most of these cases, and much time will be consumed in making a complete operation, we should have a pulmonary anæsthetic at hand.

A preliminary irrigation of the stomach provides us greater security against the inspiration of vomited fluids of a septic character; but I believe that this is a rare accident, and, moreover, free gastric irrigation with a patient bordering on the moribund state is by no means a simple or safe procedure. The patient should be catheterized and given an enema as large and hot as can be borne, before the operation is begun.

Technic in Operating.—Anything like hasty, haphazard operating on parts within the peritoneal membrane is to be deprecated, while on the other hand, unduly prolonged anesthesia greatly depresses the vital powers; besides awkward, unskilful or long exposure of the peritoneum tends to deepen shock and paralyze the intestine.

It is, therefore, presupposed that one properly equipped to operate for strangulated hernia has mastered the technic of intestinal surgery, by practice on the cadaver, or, what is much better, by experimentation on the anesthetized animal.

Everything in readiness, we begin by making a long, free incision passing down over the tumor, in an oblique direction. This cut should begin from 3 to 4 inches above the internal ring in inguinal hernia. It should extend far enough down to permit easy manipulation of the sac. McBurney's advice to commence the deep dissection close to the neck of the sac and work downward, is a good one. When the general condition warrants it, the whole distended sac should be isolated and turned out before it is opened. This is usually a rapid and simple procedure. We now come to dealing with the structures after opening the sac. In several cases I have found that the constriction was not so tight, but the trouble rather depended on torsion of the bowel; though, again, we may sometimes find the constriction so extreme as to more or less completely cut through one or both coils; in some cases we will

find that the pressure has been so great as to quite freely induce an annular erosion through the fibrous coat, or even open the intestine. The division of the constriction should always be from without in, freely exposing this to the naked eye. There should be no more moping and cutting blindly with so-called "hernia-bistouries." All the divided vessels should be separately secured and ligated until the peritoneum comes into view, when the inner aperture—miscalled a "ring"—is divided with a blunt-pointed scissors. We now lay the neck of the sac widely open and draw the intestine *well out* and critically examine it. If there are any adhesions, they should be freely liberated; then, if the intestine possess full vitality, it should be carefully pressed up into the abdomen, the sac cut away, and a radical cure superadded, the latter prolonging the operation but a few moments and accomplishing the double purpose of relieving the strangulation and obliterating the hernia.

The second step of the technic for radical cure should be as simple as possible, as it appears from statistics that those who have survived the operation for strangulation at any time, have rarely, if ever, had hernia again. Ample drainage with scrupulous aseptic precautions will usually secure prompt union in recent, noncomplicated cases.

Laparotomy Incision.—In all cases of strangulation, in order that we may ascertain a full knowledge of the condition of the intestine, *above* the constriction, or internal to it, besides for the purpose of aiding manipulation in dealing with complications and rendering reduction easy, the scalpel must be carried freely up through the ring into the abdominal wall. Neglect to more freely explore in former times, cost the lives of a large number. Mr. Knaggs impresses the importance of completeness in operation in these, and records two instances within his own observation, in which failure resulted through neglect to examine and liberate the upper segment of the intestine. In one, gangrene from volvulus of the distal coil was found on autopsy. In another, a distended unrelieved loop was found which remained after operation.

A large, free incision has been avoided heretofore because it was thought to augment shock and favor ventral hernia, but there is no evidence to show that, when properly closed at the time of kelotomy, it is responsible for either.

Complications and Varieties of Strangulation and Their Treatment.—The great mortality following kelotomy in former times resulted from incomplete operative treatment in complicated cases; and strangulated hernia at any stage may be complicated. The diminished mortality of our time comes from earlier intervention with aseptic precautions and the deliberate and precise management of complications. As an evidence of reduction of mortality, a few recent statistics may be cited from recent contributors.

One writer has collected 227 cases of strangulated hernia operated from 1861 to 1864, giving a mortality of 75%. Benno Schmidt, in 1883, reported that at that time in the German hospitals there was 36% mortality. Tschering, of Copenhagen, in 524 cases, gives the death-rate as 29%. Southam and Bolby, in 1895, in the London hospitals, found that mortality ranged from 40 to 43%. Borchard and Dagot, of France, the former 17%, the latter 14%, when not complicated. Borchard sets the present mortality at 7% after kelotomy for strangulation. Gussenbaur said that anti-

septics had reduced the mortality to 39%. Hengeler, for 15 years prior to 1897, collected 1,491 cases of kelo-tomy, mortality 16.5%. I am sorry to say that no recent statistics under this head are published in America, as I am confident that they would show an average of less than 5% in noncomplicated cases. In my own early experience, fully 75% sank after operation; now, unless the patient is in deep collapse at the time of operation, recovery in all is quite the invariable rule.

Complications.—The complications attendant on strangulation are constitutional and local.

In many, especially the female, they are of an alarming character, from the beginning; pain is agonizing, vomiting is incessant, the circulation is enfeebled and great exhaustion sets in early. In others, again, strangulation runs into gangrene or even perforation without any violent disturbances of the system, until late.

General Condition.—The sudden and complete occlusion of the intestinal canal usually produces profound disturbances of the system; but fortunately in strangulated hernia, the obstruction is seldom immediate or total; when it is, mortal changes set in early.

The patient is first seized with agonizing pain over the abdomen, vomiting begins, the pulse quickens and is weak, signs of prostration set in early, the extremities become cold and damp. As the condition continues, reverse of peristalsis sets in and fecal vomiting commences, with great thirst; the tongue is livid, dry and crusted and the gums besmeared with sordes. The patient lies on his back, in deep melancholy or in a state of indifference.

To the inexperienced, many of these cases at first sight strike one as past any hope of relief or in no condition to warrant radical surgery. But I am acquainted with no serious condition that is so susceptible of effective and prompt remedy by judicious operative intervention, provided only that the pulse is regular and can be felt at the wrist. In extreme cases their transport to hospital by any sort of conveyance is a trying ordeal which greatly augments their exhausted state.

Pain has greatly enfeebled the heart, fecal toxemia is in operation, and the task before us is to release the intestine and restore the free movement of the intestinal current without augmenting shock.

Next to the rough transport of the body in a grave case of strangulation, the most potent cause of deepening shock is full, pulmonary anesthesia. With a knowledge of these facts, it therefore behooves us to send these cases into hospital early, revive the sinking powers by very warm, large, stimulating enemata and proceed with the first stages of the operation until the intestine is fully liberated, under ethyl chlorid and cocaine.

The fullest measure of success in the operative treatment will only be realized when special remedial measures are primarily directed toward combating grave constitutional conditions.

Unrelieved Strangulation Leads to Local Changes and Lesions in the Imprisoned Intestine.—1. Deep asphyxia or incipient gangrene. 2. Plaques of gangrene or ulceration of intestine. 3. The entire circumference of gut may be mortified. 4. Gangrenous perforation with fecal extravasation into the sac.

Intestinal Asphyxia.—What is the most embarrassing of all, is that comparatively large class of cases in which we are in doubt as to the vitality of the intestine. It is of a deep brown chocolate color, congested and

thickened; it has a leathery feel and seems to be devoid of circulation. The application of very warm water fails to elicit any positive evidence of circulatory stability. The gut is not healthy nor is it dead; but, as Treves says, is *hors de combat*, or rather, "knocked out." It is in a state of deep asphyxia and may recover its full functions, or may not. The intestine is in a state of impending gangrene, or is rather in the incipient stages of mortification. Jordan Lloyd well observes in this connection, that "the recognition of gangrene in a coil of intestine lying before us in an open sac is not always an easy matter. Few surgical complications are more perplexing than that of determining whether a coil of gut shall be returned to the abdomen or be treated where it lies. No judgment can be formed merely by the color of the coils, nor can any analogy be drawn from one's experience of gangrene of the outer surface of the body."

But we certainly cannot agree with this eminent surgeon when he continues and adds that, "the same amount of functional disturbance in the nutrition of an external part, as a finger or toe, for example, which necessarily will be followed by local death and putrefaction, may be entirely recovered from in the case of the intestine, if the cause of the disturbance be removed and the gut be returned to the peritoneal cavity under aseptic precautions."

We cannot remove the cause by the reduction of a mortally asphyxiated coil of gut, and function never returns to mortified tissues in any part of the body. The damaged intestine certainly does possess most remarkable properties in the way of spontaneous repair; but to return a strictured, crippled, dying or dead intestine, a foreign body, a septic structure into the peritoneal cavity is certainly to invite disaster. And therefore, we regard the advice of Mr. Carwardine as certainly not *en rapport* with modern rational treatment, when he says, in speaking of these doubtful cases, "When in doubt in strangulation, the belly is the best place for the gut."

There can be no question but resuscitation may occur in rare cases, that gangrenous patches may become innocuous by adhesions, that spontaneous anastomosis may occur, or, what is more remarkable yet, the dead segment of gut may find its way out through the anus.

What then should be our line of action in this class of doubtful cases? Clearly, with our knowledge of the physiology of the alimentary canal, that large segments of it may be removed with perfect impunity, we need not hesitate to amputate the suspicious part. And now that the technic of resection and jointing have become *au courant* procedures there should be no hesitation as to our decision. Only one thing will at all justify the return of a suspicious coil into the peritoneal cavity; and that will be lack of skill, or want of a practical knowledge of intestinal surgery, assuming of course, that the general condition warrants it.

Localized Patches of Ecchymosis, Abrasions, Contusions, or Gangrene of the Intestine.—In nearly all cases, which a surgeon is called on to operate for strangulated hernia, the patient has been subjected to repeated and perchance violent taxis before he sees the case. Many are only sent to the hospital when they are close to the moribund state. Happily these are much less frequently seen now than 20 years ago. In all these, with few exceptions, we will find the bowel more or less traumatized.

Deep Congestion or Incipient Gangrene.—In all cases of

acute hernial strangulation, there promptly sets in simultaneously, a double stasis; *first*, of the fecal current, and *second*, of the circulation. In the first, temporary intestinal exclusion is induced, a condition which of itself, if not protracted, is not a serious accident; its lethal influence only becomes obvious when the obstruction is maintained, when decomposition of the imprisoned, stagnant, alimentary contents begins, when an excess of gas is liberated and a fresh strain is put on the intestine from below. Actual intestinal asphyxia, or gangrene, can be said to only begin when vascular stasis is established; when the arterial feeders yet send the blood into the capillaries, but the efferent vessels are hopelessly obstructed; a condition gradually extending in a retrograde direction, and later inducing a general thrombosis of all the mesenteric radicles. When this stage is reached incipient gangrene is in operation, now in the presence of this condition in which the intestine is not completely killed, in which the gut is not dead, not mortified, and yet not sufficiently vitalized to functionate with certainty, should we, if in doubt, adopt the current custom and return it to the peritoneal cavity after complete relief of the strangulation? In this connection it may be well to note that in consequence of the complete and double stenosis of the intestinal and vascular canals, decomposition has begun, and the exuded serum in the sac emits an odor which assures us that the bacterium termo has commenced the work of decomposition and the extruded loop is *septic*; it is certainly temporarily crippled and functionless.

This is one of the most numerous class of cases in the past, which led to the appalling mortality; and what, indeed, can warrant or justify the practice of forcing these dead or dying structures up into the healthy peritoneal cavity seems beyond comprehension.

Immediate Resection.—In these dubious cases, the general condition of the patient permitting it, there is but one course to pursue; and that is an immediate and complete resection of the suspected loop, whether it be an inch or a yard in length, with simultaneous jointing of the divided ends. This course is simple, rational, and safe in skilled hands and a proper environment.

Intestinal Paralysis, Intestinal Toxemia, etc.—In Gibson's recent able contribution (*Annals of Surgery*, October and November, 1900), the author observes that the above terms "are usually used as a mask for peritonitis," the functionless, infected coil, with its wall collapsed, its musculature without tone, its mucous membrane edematous and detached, and its fetid, decomposed contents transuding through its destroyed serosa, lies doubled up as a block in the path of the alimentary canal, infecting and spreading widely its septic elements through every tissue it touches. Experimental investigation and clinical observation conclusively prove that full physiological function in digestion may be preserved with the total exclusion of a full third of the small intestine; and, moreover, we have ample evidence that the mortality of resection is in no manner dependent on the extent removed, provided it does not exceed the physiological limit.

Stricture, Ulceration, Hemorrhage, and Perforation after Reduction of Damaged Intestine.—The intestine may suffer serious pathological changes and yet not have advanced to gross gangrenous changes; in fact, if the mesentery escape very great compression, without a certain inspection, we may overlook mottled patches or compressed areas, the seat of subtle but positive or-

ganic changes. At the point of compression at the inner aperture all the coats of the intestine may have become so crushed as to later undergo repair, by leaving a cicatricial contraction. Persistent diarrhea from ulceration of a compromised loop has followed with a fatal ending in some cases (Malgaigne). Persistent and fatal hemorrhage *per rectum* has, too, occurred (Paget). In one of my own cases of resection the intestine was found filled with coagulated and fluid blood.

Mr. Kough (*London Lancet*, 1884, p. 636, vol. ii) records a case of death from enteric hemorrhage two hours after reduction of the intestine. The sac contained six feet of ileum with the cecum. On autopsy, when the bowel was opened, a pint of fluid blood escaped. The inner surface of the bowel presented several dark, slate-colored patches. Death from ulcerative perforation and peritonitis in former time was not an infrequent postoperative sequela in keloctomy, when the intestine of "doubtful" vitality was reduced.

Gangrene of the Intestine.—When gangrenous changes have advanced to the unequivocal mortification or death of the extruded loop, whether it appear in patches, involve the entire circumference of the intestine, or has advanced to perforation, the part involved must be isolated from the peritoneum. How this may be attained to the best advantage of the patient embraces one of the most important chapters in the history of intestinal surgery.

Twenty-five years ago resection for gangrenous hernia was comparatively unknown as a practical procedure, though there were some few rare cases recorded since the seventeenth century. At that time and until later, there was only one alternative in cases of complications in strangulation, when the intestine was not immediately reduced, which was, to secure it to the groin and make an artificial anus.

(To be continued.)

PERCENTAGE AND LABORATORY FEEDING.*

By J. P. CROZER GRIFFITH, M.D.,

Clinical Professor of Diseases of Children in the University of Pennsylvania, Philadelphia.

It is safe to say that those physicians who have once accustomed themselves to what is known as percentage feeding, will never, if they can avoid it, use any other method. Yet considerable misconception exists, and mistakes often arise through a lack of understanding of what percentage feeding really is, and through a lack of the easily acquired knowledge of how to employ the method properly.

Let us contrast for a moment the old and the new, the empirical and the scientific plans of feeding. In the old way—the excellent way which we all followed with more or less success until we had a better plan—a physician thought of his milk mixture as consisting of so many tablespoonfuls of milk, so many of cream, so many of water, and so on. In his mind he had stored up a certain formula of this kind which represented what he considered about the proper food for a nursing child. Why we used this or another formula, the majority of us scarcely knew. We had merely learned it empirically, or oftener we had learned from some one else's experience that upon this formula the majority of children could be expected to thrive. As the babies grew older some of us often increased the

* Read before the Philadelphia County Medical Society, May 28, 1900.

proportion of milk or cream and diminished that of water in an absolutely unscientific way, forgetting that in human milk no such alteration occurs as time goes on, yet realizing that this change was sometimes necessary in our milk mixture. The real reason for the change we did not understand, and too many of us degenerated into the condition of mere manipulators of quantities by rule-of-thumb methods, saying to ourselves that at one week we would put so many tablespoonfuls of milk in the mixture, at 3 months so many more, at 6 months so many more, and so on, absolutely regardless of the individuality of the baby or its actual needs.

When the babies did not thrive upon the mixtures which rules said they should have, we made certain changes which again experience had taught to be useful in illness, but the reason for which we scarcely understood. For instance, we used whey, or barley water, or egg water as diluents instead of water, or we increased or diminished the cream or the milk in our mixture. Some of us were guided by a knowledge that curds in the stools perhaps suggested too much milk, sour vomiting perhaps too much cream, and so on, but this was about as far as we could go. In fact, it was impossible to go much farther. One family used cream of one strength from one sort of cow, while another had furnished them cream of another strength from another breed of cows. There was no certainty that the cream and milk furnished to a baby did not vary even from day to day. There was no knowledge of or control over the purity of the dairy product. It is evident that all a physician could do, and in many cases still can do, was to feel his way empirically, shifting numbers of tablespoonfuls up and down as seemed to him best. We all did it. Most of us do it yet. Often we are forced to do so. But, as I said, any one who has used the newer plan wants always to avoid this older one because the newer is so much more satisfactory in its results.

Yet studies meantime were constantly being made by scientific investigators into the relative composition of human milk and cow's milk, and all these results were published and were read by us without, it would seem, it even occurring to us that, since the results of analyses made were all expressed in *percentages* of fat and proteid, solids, salts, water and sugar, and not in *quantities* of milk and cream, it would be very much easier for us could we work directly with the decimal proportions these analytical studies had given us. This simply is what the percentage method of feeding is; the transferring of scientific analyses to practical feeding. One merely learns to think in decimal proportions instead of in teaspoonfuls or ounces. One says, "I will give the baby such a percentage of fat and such of proteids," instead of saying, "I will use so much of milk and of cream." This method greatly simplifies the whole process as well as making feeding more scientific and effectual. In the old way we might, for instance, have concluded that a child needed a richer food, but that it could not digest more curd. If, now, we added more cream to the mixture, we were at the same time increasing the curd strength and this we did not want, whereas if we substituted a certain part of milk by cream, we could in no way tell just what effect we had produced upon the proportions of the ultimate ingredients of the mixture. All is different if we think and work in percentages. We say we will increase the fat in the mixture from 3% to 4%, but leave everything else unchanged—and then we do

it accurately. Now should the mixture disagree, we know exactly what is wrong. Surely, the advantages of this must appeal to every one. Having tried both the old and the new, I can assure you that I get much better practical results with percentage feeding.

The method of calculation is easy. Any one with the slightest knowledge of figures can manage it. Several simple methods have been published. One of the most convenient and, for practical purposes, accurate, is that published by Dr. Baner, of New York. I carry his few equations with me, written on a card and kept in my pocket-book in case I should forget them. Dr. Taylor, of New York, has a modification of Baner's which is more accurate, and Dr. Westcott, of Philadelphia, has still another method. I will not occupy the time of the Society by going into the calculation. The papers of these writers explain it very clearly. For those physicians who would rather avoid even the simple calculations, convenient tables may be found in the text books of Rotch and of Holt, showing at a glance exactly how much milk, cream and sugar are required for many of the percentage formulæ oftenest used. One can readily make a copy of these and have it always at hand.

But to work in percentages it is necessary to have milk and cream of a definite percentage strength, and this is not always easy to obtain. We may, however, assume that in ordering herd milk the percentages of sugar and of proteid vary very little. The variable ingredient is the fat. In these days when the centrifuge for the examination of urine has become so cheap and so convenient, it is very easy for any of us to test a few times the fat strength of herd milk and cream, and then to calculate a formula which we can readily modify according to the needs of the baby. I do this myself repeatedly and yet am devoid of special knowledge of chemistry or mathematics. It is mere mechanical work.

Where cream and milk of definite guaranteed strength can be obtained, all the trouble of home analysis can be saved, and where a milk laboratory is accessible the physician may be spared even the labor of a calculation or the trouble of consulting a table.

This brings us to the consideration of the milk laboratories as managed by the Walker-Gordon Company in various of our larger cities. There is to some extent a misconception of the purpose and nature of these institutions. Some have even imagined that a special sort of milk-food is prepared there, like a patented food; and others talk of laboratory milk agreeing or disagreeing as though it were an entity, with its composition always the same. A milk laboratory is simply a place where you order for a baby anything you want in the way of a food, put up in any way you please. There is nothing whatever special or peculiar about it. The milk is just like all other milk except that unusual care is taken to have it clean and free from germs, and that its strength in the different ingredients is determined daily by analysis and is guaranteed. Such milk and cream can be procured by families at little above the ordinary rates, and the milk mixture made at home by the mother or nurse according to the directions of the physician and according to the formula furnished by him. Such guaranteed milk and cream can be obtained in some places from other dairies than those of the Walker-Gordon Company. The Philadelphia Pediatric Society is looking forward to a near future when it shall have completed arrangements by which guaran-

teed milk and cream can be obtained from many dairies of Philadelphia.*

But since even with definite-strength milk and cream the calculation of a formula by the physician is necessary, with a milk laboratory handy he can even, as I said, save himself this, and the mother the trouble of preparing the food, by having the mixture made at the laboratory, put into the different feeding bottles there and delivered at the home all ready for use. The physician in this case must write a prescription ordering the percentage of fat and of proteid, etc., and specify how many bottles are to be supplied and how many ounces these shall contain. Anything you please may be ordered in the mixture. Barley water or oatmeal water, malt extract, pancreatic extract, even patented foods if you wish. It is the laboratory's business to follow your directions just as a drug store would.

There has been some little talked and written about the milk and cream of the laboratory being "Separator" products and therefore, it was said, inferior. One should not forget that all cream from large dairies is nowadays separator cream. Milk-men do not any longer skim with spoons and hand skimmers and the like. The triviality of such an objection is therefore evident. Nevertheless, if you want skimmed cream from the laboratory, order it and you get it.

Finally, it is, of course, necessary, as with all infant feeding, to know what to expect from the different ingredients of the food, and to acquire by actual experience a little knowledge of the proportions which a baby is liable to require, and what changes a certain baby needs at any time.

One of the secrets, if we may call it this, of successful feeding of very young infants is to begin with low percentages. Woman's milk contains: Fat 4%, proteids 1 to 1½%, and sugar 7%. Yet, it is by no means advisable to start any baby upon this strength of a milk mixture. We must remember that we are not dealing with the natural food of the child. The proteid of milk is a complex substance which varies in different animals. That of the cow is distinctly different from that of the woman. It is unreasonable to expect, then, that a baby can take it in just the proportions found in human milk. This is the mistake which some physicians have made in their first efforts at percentage feeding.

The child in the first two weeks of life should not be started with over .50% proteids. In fact, even much later in the first year it is wise to begin percentage feeding with low proteids in the case of children who have been fed on food other than milk or who have been subjects of indigestion. In all cases where we find the existence of diarrhea with numerous curds in the stools, it is well to consider whether the proteids had not better be reduced at least for a time, although it is well to remember in this connection that these appearances are not infrequently composed of fat. It is the proteid element which is the hardest for most children to manage.

Then with regard to the percentage of fat. Here, too, it is well to begin with small amounts—2%, perhaps, instead of the normal 4%. When we find a constant tendency to rancid vomiting it is very probable that the fat is too high even though the vomit may contain curds. The sugar sometimes acts upon the bowels and in other cases causes gastric indigestion. Less than the normal 7% of sugar is good, then, for a beginning—possibly 5 or 6%.

For a very young baby, therefore, without signs of disease, or for a marantic child who has had constant symptoms of indigestion, such a percentage formula as fat, 2%, sugar, 5%, proteids, .50%, would not be amiss. Of course, it is not to be expected that this weak mixture will answer long. It must soon be increased and the method of increase will depend largely on circumstances. Other things being equal, it is generally my plan first to increase the fat by steps up to about 3%, then the proteids to .75 or 1%, and perhaps meantime the sugar as well, watching constantly for the development of any unfavorable symptoms and altering the formula according to the nature of these. Most important is it to weigh the child weekly or semiweekly. If increase in weight does not go on properly in spite of the existence of no symptoms of indigestion, it is nearly certain that the food is either not strong enough or not large enough in quantity. On the other hand, we must remember that there is no reason to increase the strength of the food when the child is gaining nicely. There should be absolutely no rule of thumb increase of the percentages of any of the ingredients dependent upon age alone. It is the condition of the individual child which must determine this. I cannot too strongly emphasize this point. Your rule should be, "Let well enough alone." Of course, one does not wait for actual failure of good condition to develop. But a little experience and judgment will soon teach how to proceed in most cases. One must remember, too, that failure to increase in weight may depend, not so much on trouble with the percentage formula, as upon the fact that the baby needs a larger quantity of nourishment. The baby at the breast, although it does not get stronger food, takes a larger quantity as it gets older.

An eminent writer, for whose knowledge of the diseases of children I have much respect, has recently expressed the belief that children raised upon milk mixtures furnished by a laboratory experienced difficulty in tolerating an increase in the percentage of proteids. As already stated, very many children have difficulty in digesting the proteids of cow's milk given in any way whatever; and, in any case, before these are increased we should be sure that such an increase is really indicated. That there should be any such special difficulty in the digestion of proteids in the case of laboratory milk, I find it impossible to conceive. My own experience is in accord with that of those physicians who have used milk laboratories very extensively in other cities, viz: that there is no special difficulty in increasing proteids or any other ingredients of laboratory milk mixtures more than with any other milk. That laboratory milk offers any especial difficulties seems to me to be an assumption lacking proof.

Of course idiosyncrasies of all sorts exist and all sorts of changes have to be made and expedients used in infant feeding, as we all know, but these are exceptions and not the rule. I once knew a baby who thrived only after its mother fed it exclusively on cornmeal mush. But this could hardly be our guide in practice.

After all, before we can come to any conclusion that percentage feeding or any other feeding is not succeeding in a given case, we must be sure that the error is not with our own formula or method. The following case illustrates my meaning:

I was called to see a baby in consultation with a well known and able obstetrician of this city, who frankly acknowledged that the feeding of such a case

* Since this paper was written four dairies in the vicinity of Philadelphia are receiving certificates from the Philadelphia Pediatric Society.

was out of his line and asked me to take it in charge. The history is as follows:

F. W., born June 16, 1891. He weighed over 2 pounds at birth. Feeding had always been difficult. He had had malted milk and peptonized milk, but neither suited. Then he was put upon a laboratory percentage mixture at first of fat 3%, sugar 6%, proteid 0.50%; then fat 2%, sugar 5.50%, proteid .50%; then fat 3.50%, sugar 6%, proteid .28%; then fat 3.75%, sugar 6%, proteid .50%. But whenever the proteids exceeded .50% the child vomited. Colic was troublesome. I saw him for the first time on November 15, 1899, and found a very thin child of 5 months (22 weeks), weighing about as much as when born. His face was bright and his strength seemed very good. After some study of his history and condition, I gave it as my opinion that the trouble was not with the proteids, but with the fat being in excess. This seemed likely from the fact that the child showed a tendency to vomit, but never had diarrhea or the passage of undigested milk. I advised that the fat be reduced to 3% and the proteids increased to .66%; a greater amount than had been given for a long time. I also advised adding some barley water to the mixture, since experience shows that this often seems to render proteids more easily digestible. The sugar was also increased slightly in order to aid in overcoming constipation. The formula then read: fat 3%, sugar 6.50%, proteids .66%, $\frac{1}{4}$ barley water, $\frac{3}{4}$ water.

The further history of the child is one of almost uninterrupted gain except for a short time when it suffered from an intercurrent malady.

Weight Chart of F. W.

The changes in the food formula were as follows:

	F.	S.	P.
23 weeks	3	6.5	.66
29 "	3	6.5	.75
29½ "	3	6.5	1.
34 "	3.5	7.	1.
39 "	4.	7.	1.

Studying these and the weight chart conjointly is interesting. The loss in weight at 26 weeks was the result of a too great temporary dilution of food done through a misunderstanding on the part of the family. The cessation of increase about the 29th week was followed by immediate gain after the food-strength was increased. The same renewed gain occurred at 34th week. The cessation of gain from the 39th to the 42d week was the result of the intercurrent affection.

The following case is another instance of the folly of condemning a good thing which we have not learned to appreciate:

Mary C., born September 17, 1899. First seen December 29, 1899, when 3½ months (16 weeks) old. The 4 preceding children had all been cases of inanition, and had all died in the first 7 months of life. Only the first 2 children born, which had been breast-fed, survived. The child Mary, weighed it was said, 11 pounds when born. This is certainly an overestimate, but it must have been a large and plump baby. She was fed at first on barley water and milk, but did not grow, then was given a percentage mixture from the Walker-Gordon Laboratory, but did not do well, suffering either from diarrhea or vomiting. Four different formulae were tried. It should be stated, however, that the physician in charge had never proscribed percentage milk before, and did so now only on the insistence of the family. It seems likely from the bad results that he did not consider the relation of the different ingredients to the symptoms. At last, another physician was called in who prescribed Robinson's barley with condensed milk. With this food constipation replaced diarrhea and there was much colic, but there was no gain in weight. The child weighed only 8 pounds and 1 ounce when I first saw it. It was in a wretched condition, wrinkled, puny, and crying constantly from pain. I strongly urged the employment of a wet nurse, as I was doubtful about the recovery on other milk. The mother, however did not consent, owing to her prejudice in the matter. She had in any case made up her mind from her past sad experience that the recovery of the child was absolutely hopeless. I ordered for it a percentage mixture from the laboratory of the strength of F. 2%, S. 6% P., .50%; 8 four ounce bottles. Although this mixture was weak, I warned the mother that it might disagree badly, which it did, causing severe vomiting. After 24 hours' treatment with alternate egg water and barley water, the formula was changed to F. 1.50%, S. 5% P. .50%, with barley water. The fats were reduced on account of the tendency to vomit. This formula agreed nicely, colic nearly ceased and constipation was much less. The improvement has been nearly constant and brilliant, barring a few times when the child suffered from a bronchial catarrh.

Weight Chart of Mary C.

Changes in the formula were made from time to time as follows:

	F.	S.	P.
16 weeks	2	6	.50
16½ "	1.50	5	.50
19 "	2	5	.50
20 "	2	5	.75
24 "	2.50	6	1.
26 "	3.	7	1.
30 "	3	7	1.25
33 "	increased quantity merely.		

Comparing this with the weight chart we notice no gain of weight during the first three weeks of treatment. The only effort at this time was to accustom the child to milk. Of course, the formula was too weak for any material improvement to be expected. It is interesting to note the decided increase of weight which followed the slight increase of the fat percentage

at 19 weeks. The growth was now fairly satisfactory, the strength of the food being gradually increased toward the normal human milk percentages. The decided gain at the 33d week followed an increase in the amount of milk given without any alteration of the formula. The little girl now is like a different child. She is well filled out and gaining constantly. My plan is to increase the fat up to 3.50 or even 4 and the proteids possibly up to 1.50 according to the needs of the case. Later the proteids will require a still greater increase.

Still another case may be cited in illustration of the point I wish to make, viz: That we must bring our common sense to bear in feeding an infant by any plan, and not hastily condemn any method because it seems to fail. The following case was by far the most unpromising of any I have attempted to feed for some time.

L. M., born June 12, 1899. Seen by me January 27, 1900, at the age of 7½ months (33 weeks). The child was said to have weighed 11 pounds when born; doubtless an overestimate, but an indication of his excellent size and condition. He was fed on the breast and the bottle for the first two months and then was given the bottle alone, first of malted milk and then of condensed milk, but always suffered from diarrhea. Next he was fed upon some "sterilized milk," and then upon percentage milk prepared at the Walker-Gordon Laboratory. This was given for several weeks, but disagreed. I do not know the formula employed. The child then received a rather strong cow's-milk-and-water mixture, which he vomited. Next, for two months, he had barley water, brandy, and white of egg, and for the last month had Mellin's Food. With every sort of feeding he had diarrhea, and always passed curds if there was any milk in the food. He had lost weight constantly since birth, and for the last few weeks had some edema of the cheeks and feet.

Examination showed a wretched-looking marantic specimen. The abdomen was distended, the limbs very thin, the cheeks unnaturally plump from edema, and the feet and legs distinctly dropsical. I ordered him a formula from the laboratory of F. 1.50%, S. 5%, P. 50%, with the water one-half barley water, and of an alkalinity of 10%, i. e., $\frac{1}{10}$ of the whole mixture was lime water. The low percentages were chosen on account of the child's extremely weak digestion. An astringent mixture was also prescribed. By February 2 the child seemed better in every way. There were but two stools a day, but there was no gain in weight. An increase in the formula was made to F. 2%, S. 5%, P. 50%. By February 7 the child seemed clearly better and the flesh fuller, although the weight was apparently no greater. At this date it weighed 7 pounds 10 ounces. It is probable that the earlier weighings were incorrect and that the weight at the thirty-third week was little over 7 pounds.

Improvement was doubtless interfered with by the devel-

opment, about February 17 (36 weeks), of a very severe bronchitis with high fever, possibly a bronchopneumonia, and then a few days later of symptoms of scurvy. In spite of this, gain in weight went on, as the chart shows. The baby has improved wonderfully and is now in excellent condition, with every prospect of a complete recovery. It is, of course, still far below the normal weight for its age. The food is still weak for its age, as it is now almost a year old. I shall now increase the proteids of the food as rapidly as the digestion permits and the rate of growth indicates it necessary.

The various changes in the formula were as follows:

	F.	S.	P.
33 weeks	1.50	5	0.50
33½ "	2	5	0.50
35 "	2.50	5	0.75
36 "	2.75	5	1
37 "	3	5	1
37½ "	3.50	6	1
38½ "	4	7	1
47 "	3.50	7	1.25

Comparison of this table and of the weight chart requires some explanation in view of certain symptoms. From the 38th week to the 42d, gain in weight, though steady, was not as great as it had been, in spite of the increase in the strength of the formula. This appears to have been due to a continued slight indigestion following a severe attack of vomiting and diarrhea at 38½ weeks. After this was over the gain was striking with no alteration of the food-formula. The loss in weight at the 45th week was the result of a very severe cold with diminution of the appetite. The diminished rate of gain up to the 47th week seems clearly due to diluting the milk with water, not advised by me, but done by the mother on account of a tendency to vomit which the baby showed. I consequently ordered this dilution stopped and reduced the percentage of fat slightly although increasing the proteid. The resulting gain is shown in the chart.

I could detail many other cases showing how well children do either on percentage formulæ as prepared by the laboratory or on percentage mixtures made at home from definite-strength milk and cream; some of the children being fed from birth on percentage-milk, some doing finely after little success with other methods; many of them with weight-charts in which the curve is up to or even above the normal curve of healthy, breast-fed children. But I have limited myself to these three cases, partly because the children were such absolutely unpromising specimens which had been doing badly on all methods tried, largely, too, because all three of them had at different times been fed on laboratory prescription milk before I saw them and had done very badly indeed. One could easily have claimed that this was the fault of laboratory feeding. As a matter of fact it must have been the fault of the prescriptions which had been ordered. What I succeeded in doing for them of course any physician can accomplish. All that is needed is that he go about it with some common-sense idea of what he is trying to do.

A CONTRIBUTION TO THE TECHNIC OF THE WIDAL TEST.

By A. ROBIN, M.D.

OF NEWARK, N.J.

From the State Board of Health, Newark, N.J.

The Widal test has already passed the experimental stage, and now is universally recognized as an almost

pathognomonic sign of typhoid fever. It is also being utilized for the recognition of infection with virulent *coli communis*, pneumonia and tuberculosis, and hog cholera in animals. The conditions necessary for the successful application of the test are a motile organism, or one which is capable of clumping either when the blood is added to a test-tube culture (macroscopic test) or a hanging-drop (microscopic test). Whenever these conditions are present the test can be employed for diagnostic purposes. The opinion is gaining ground that the reaction is one of immunity and not infection. Personal observations fully corroborate this view. The reaction has been observed in mild or so-called walking cases of typhoid fever, while on the other hand it bears no relation to the severity of the disease, and in one case submitted to the laboratory it was absent 24 hours before death occurred. It may also be absent until convalescence is well established. Add to this the fact that it is frequently observed in healthy individuals when the blood is diluted 1:5 or even 1:10 and that it persists for months and even years in persons who have suffered from an attack of typhoid fever, and we have an incontestable array of arguments in favor of the above view.

Those who still believe that they can make a diagnosis of typhoid fever without the aid of the Widal test will probably be surprised at the assurance that typical cases, as pictured in our text-books, are not met with frequently. Many lack one or more of the pathognomonic symptoms of the disease, making it impossible to arrive at a correct diagnosis during the first week or two of the attack. From the blanks filled out by the attending physicians, when submitting a specimen of blood for examination to this laboratory, we gather the following interesting data: Of the cases submitted during the first, second and a few the third week of the disease there was diarrhea in 30%, enlarged spleen in 32%, iliac tenderness in 46%, rose-spots in 27%, and delirium in 20%. We have no record of epistaxis, but it is well known how infrequent the occurrence of this symptom is. It is thus seen how difficult, nay impossible, it may be to make a correct diagnosis from clinical symptoms alone.¹

We often hear it stated that typhoid fever has undergone considerable modification within the last few years; the disease is milder than it used to be and the mortality is less. Is it not probable that besides the improved sanitation and treatment, the cause may be sought in improved methods of diagnosis? At present we recognize mild cases which in the olden times passed under the name of *bilious fever*, *bilious remittent*, or *remittent fever*, not to mention the cases frequently encountered in which the typhoid lesion is confined to some other part of the body besides the intestines, and which in times happily gone by formed medical puzzles. There are still physicians in Delaware who claim that they have never seen a genuine case of typhoid fever; their patients suffered from remittent fever, and yet during an experience of almost two years *plasmodium malariae* was demonstrated in the Delaware State Board of Health Laboratory only in half a dozen cases, while on the other hand every case of so-called remittent gave the Widal reaction.

The usefulness of the test, however, depends entirely on the *modus operandi*. Were we able to use both the

macroscopic and microscopic methods in every case, an error would be almost impossible, but the difficulties connected with the macroscopic method are sufficiently great to form a permanent barrier to its employment, and we must, therefore, rely upon the microscopic method, especially in municipal laboratories. This being the case, the technic must be faultless, or mistakes will occur with sufficient frequency to make the results unreliable. In municipal laboratories the chance for error is still greater, since the bacteriologists are mostly overcrowded with work and can devote but a few minutes to each specimen.

The problems confronting us in applying the test are: 1. The dilution. 2. The best way of obtaining a motile culture free from "natural" clumps. 3. The differentiation between a true and a pseudo-reaction. 4. The time limit.

1. The necessity for high dilutions (1:20 to 1:40) is made evident by the observations of bacteriologists in this country and abroad that the difference between normal blood and that of typhoid patients is one of degree and not of kind. In dilution of 1:5 or 1:10 even normal blood will at times produce agglutination. The typhoid reaction has also been obtained with the blood of tuberculous patients, even when diluted 1:25. On the other hand, no case is on record in which a positive reaction occurred with a dilution of 1:40. It is thus seen that the question of dilution is not a matter of indifference as some authorities claim. To obtain accurate dilutions various methods have been devised from time to time. It is hardly necessary to describe them. Suffice it to say that those which do possess a claim to accuracy are either cumbersome or applicable to bedside diagnosis only, while all the others are not free from error, which makes their *raison-d'être* doubtful. The method recently devised by F. D. Chester and myself² meets all the requirements, combining as it does accuracy with simplicity. It is essentially a modification of Cabot's medicine-dropper method from which it differs in the substitution of a mechanical appliance for the fingers and, what is more important, is being utilized for making dried-blood specimens. It consists of an ordinary medicine-dropper, a V-shaped piece of spring brass or nickel-plated steel and a medium-sized Hoffman clamp (see Fig. 1). The rubber bulb of the dropper is placed in the brass plate and the latter into the clamp. Each inward movement of the screw releases the bulb and draws up the blood, while an outward movement has the opposite effect. The advantages of the mechanical appliance are: (1) Not more than one drop of blood is required; (2) a single drop of blood can be drawn up without the formation of air bubbles, as is the case when the fingers are used; (3) if the puncture is not sufficient to cause a free flow of blood, a part of a drop may be drawn up, the dropper laid aside, the finger or lobe of the ear squeezed until more blood exudes, the additional portion again taken up, and the process repeated if necessary until a full drop is obtained. All this can be done without breaking the continuity of the column of blood in the dropper. (4) The parts of the appliance are to be found in every laboratory or easily obtained, and can be put together in a few minutes. The drop of blood thus obtained is expelled upon a

FIG. 1.—Appliance for drawing up one drop of blood.

¹ Dr. Katerer has kindly called my attention to the fact that the above statistics are not in accord with the observations of Murchison, Osler, Wilson and others. I am in no way responsible for the statistics above given. They were compiled from the blanks filled out by the attending physicians. I do not quote the statistics of the gentlemen mentioned, for the reason that I intended to give my personal observations only.

piece of heavy filter paper. The drop should be allowed to fall of its own weight. When the test is made the spot formed by the blood is cut out, placed in a watch glass provided with an accurately fitting cover made air-tight by a layer of vaselin, and 10, 20, or more drops of normal salt-solution, bouillon or distilled water added. In a few minutes all the constituents of the blood, except the fibrin, will be completely dissolved out and ready for the test.

2. To obtain a motile organism is not difficult. All one needs to do is to get from any of our bacteriologists a pure culture of typhoid bacilli well tried as to their motility. Such cultures may be kept in hermetically sealed tubes without impairing their motility. We keep our cultures in tubes sealed in the flame. The last one opened was sealed 8 months ago and the bacilli were found none the worse for this long confinement. To make the test it is necessary to have a fresh agar or bouillon culture which is made from the stock-culture and kept in the incubator for 18 to 24 hours. I found, however, that the incubator temperature is unnecessary and that just as good, if not better, results are obtained when the organism is grown at the temperature of a fairly warmed room. In the latter case the bacilli are longer and have a greater motility. My experience with the bouillon culture has been rather unsatisfactory, and I have long abandoned it, using a combination of both the bouillon and agar cultures, in the following manner: An agar culture is made and placed in the incubator or kept at room-temperature for 12 to 18 hours, when

3. The differentiation between a true and pseudo-reaction forms the most important and the most difficult part of the test. Natural clumps, as stated above, will form in bouillon even without any admixture of blood, and again some clumping will result upon the addition of normal blood. When the latter possesses, as it often does, bactericidal properties, the bacilli will be rendered immotile and a number of them will gather around debris, clumps of fibrin or blood-corpuscles, thus simulating a clump-reaction very closely. Only an expert eye is able to cope with such deceptive appearances. However, when the methods outlined above are followed,

FIG. 3.—SLIDE WITH TWO CONCAVITIES.

the natural clumps will not be present nor will the fibrin and other foreign material which remain entangled within the meshes of the filter paper. To still further insure against the possibility of error the following method has been adopted: A slide with two concavities is employed (see Fig. 3), the edges of the latter being surrounded with a layer of vaselin. On each of two clean cover glasses is deposited a loopful of the culture; to one a loopful of the blood diluted 1:20 to 1:40 is added, while the other serves as a control. By shifting the slide from one cover glass to the other the slightest difference in the behavior of the bacilli can be easily noted. Furthermore, the lens is focused on the edge of the hanging-drop where the bacilli are more numerous and being nearer to the objective are seen more clearly. If the reaction is positive all or nearly all the bacilli will be found to gather in clumps of two, three or a dozen and will soon lose their motility while in a pseudo-reaction only a few clumps will form, the rest of the bacilli remaining separated. If killed by non-typhoid blood they become motionless but still remain single. The difference between the true and false reactions is well illustrated in Fig. 2, C and D. In case of doubt, or when the bacilli are very small, an oil-immersion lens will render valuable aid. In fact, the Widal test can generally be more satisfactorily performed with an oil immersion. The individual bacilli, the clumps and the entire field of vision can be seen to better advantage.

4. The time limit which determines a positive reaction is another very important point. Bacteriologists abroad make their dilutions 1:100 to 1:500 and extend the time of observation to 2 hours. If within that time clumping and loss of motility does not take place, the reaction is negative. In this country, where no accurate dilutions are practised, considerable difference of opinion exists as to time. Thus, while visiting some of our bacteriologic laboratories, the author found that in a few of them the time during which a positive reaction is to take place is set at 1 to 2 minutes, while in others it is extended to 1 hour. Such a divergence of opinion cannot but lead to erroneous results. Uniform results can only be the outcome of uniform methods, and it is to be hoped that before long a certain time limit will be universally adopted. The author would propose the following: Dilution 1:10, time limit 5 to 15 minutes; 1:20, 15 to 30 minutes; 1:40 to 1:100, 30 to 60 minutes; 1:100 to 1:200, 1 to 2 hours. That would

FIG. 2.—A. Pure culture of typhoid bacilli, hanging drop. B. Bouillon culture, 24 hours, showing false clumps. C. Pseudo-reaction. D. Typical Widal reaction.

either 2 or 3 loopfuls are transferred into bouillon until a marked turbidity results, or a small quantity of bouillon added to the agar culture, and enough of the growth scraped off to produce a uniform cloudiness. By this method the natural clumps so frequently observed in bouillon cultures (see Fig. 2 B) are entirely avoided. The addition of the bouillon to the agar culture is preferable to mixing a portion of the latter in a watch-glass for obvious reasons.

mean that if within the specified time a considerable number of bacilli are found actively motile or, if dead, fail to arrange themselves in clumps, the reaction is to be pronounced negative, irrespective of the clumps which have already formed.

In conclusion it may be stated that there is no reason why the general practitioner who is removed from municipal laboratories could not perform the Widal test himself. The culture tubes and other accessories can be purchased in any supply store, no incubator is necessary, and the skill is just such as should be possessed by any intelligent physician who had received his instructions in an up-to-date medical institution.

RUPTURE OF THE RECTUM AND HERNIA OF THE INTESTINES IN AN INSANE MAN.*

By A. R. MOULTON, M.D.,
of Philadelphia.

First Assistant Physician for Men, Pennsylvania Hospital, for the Insane.

The case which I report is that of a man 34 years of age who was admitted to the Pennsylvania Hospital for the Insane during the summer of 1892. His excitement, which was very intense, was followed in a few weeks by a condition of melancholia with stupor, which in turn was succeeded by dementia. His physical health was not good, and his vitality was low. The habits of the patient were uncleanly, and he acquired the ability to produce rectal prolapse, which he did by introducing his fingers through his anus and withdrawing them with the tips widely separated. Then, if he had the opportunity, he would cause an inversion of the rectum, sometimes fully 6 inches in length. The replacement of the parts was done with difficulty by manipulation, but they would return readily by the application of moist heat with rest in bed.

On the morning of November 20, 1900, the patient got up, was dressed, and took breakfast as usual, after which he went to the water closet. In a few minutes he was seen to cross the corridor, coming from the bath-

room, and to sit down on a sofa. He was pale, and his trousers appeared wet. Supposing he had soiled himself, the attendant was in the act of removing the patient's clothes when he discovered a loop of small intestine fully 2 feet long hanging from the man's anus. There was also protruding considerable mesentery. He

had ruptured the walls of his rectum, and through the opening the small intestines and mesentery had escaped. No inflammation occurred, but the shock was profound and death occurred 36 hours after the receipt of the injury.

The accompanying photographs, one taken before and one after death, show quite plainly the magnitude of the protruding mass.

REMOVAL OF THE RIGHT UPPER CERVICAL SYMPATHETIC GANGLION FOR THE RELIEF OF GLAUCOMA SIMPLEX.

By D. H. COOVER, M.D.,
Denver, Colorado.

Professor of Ophthalmology in Grass Medical College, Oculist and Aurist to the Arapahoe County Hospital, St. Anthony's Hospital, and to the National Jewish Hospital for Consumptives, Denver, Colorado.

JOHN L., aged 65 years, consulted me March 15, 1900, with the following history: For the past year his vision had been failing very rapidly until at this time vision was reduced in right eye to only light-perception in the extreme nasal side of retina (temporal field), tension + 3, optic nerve cupped, pupils slightly dilated and fixed, arterial pulsation, and retinal vessels contracted. Left eye, vision $\frac{20}{500}$, tension + 2, nerve cupped, pupil slightly dilated, field contracted.

He never complained of pain or inflammation in either eye. Myotics were tried but had no effect upon the vision. I suggested the operation of sympathectomy to him, but before he consented I called in Dr. Melville Black; he agreed that it was a case of glaucoma simplex and would be a good case for the operation. I explained to my patient the operation and its possibilities. Dr. Leonard Freeman, of this city, removed the right upper cervical sympathetic ganglion. The operation was rather difficult, as the patient, a blacksmith, had a very short thick neck, the muscles being very large and the veins numerous and dilated almost to a condition of varicosity. The nerve was reached by dissecting down behind the sternomastoid muscles and turning up the sheath of the great vessels.

Results of the Operation.—It was performed at 5 P.M. of the 31st day of March, 1900. Immediately after the operation tension was lowered in both eyes. The following morning right pupil slightly contracted, slight lacrimation, which was noticeable during the day. Tension + 1 and more light-perception in the eye.

Second day—Tension + 1. Pupil slightly contracted and slight reaction. No pulsation of retinal arteries, vessels fuller, no lacrimation, counted fingers at three feet.

Third day—Tension + 1. Counted fingers at five feet, field of vision increased.

Fourth day—Tension + 1. Field of vision increased to median line, pupil reacted slightly.

* Read at Philadelphia County Medical Society, February 13, 1901.

ride of hundreds of miles, perhaps, on the trucks of a fast-going passenger coach, the front end of a freight car, or even to withstand the luxuries of an empty box car. Thus is accounted for the paucity of all the diseases peculiar to the female, which are so satisfactorily treated here. Again the same can be said of the poor rheumatics and paralytics and those suffering with stomach, liver, kidney, intestinal and bladder diseases, in fact, an absence of most all patient whose strength and vitality were well nigh exhausted from disease.

In this Chart are included 2 cases which have already been reported separately. One, that of a case of re-infection of syphilis, published in the *Journal of Cutaneous and Genito-Urinary Diseases*, in August, 1896; and the other a case of acute double hydrocele, due to secondary syphilis, published in *The Hot Springs Medical Journal*, in March, 1898.

Among the interesting and unusual cases, of which there were many, I have selected the following 6 which seem of sufficient importance to bear special mention. A detailed report of cases not being admissible at this time, I trust that in practising brevity it has not entirely robbed them of value.

CASE No. 715 was partial paralysis of the lower limbs, incontinence of urine, severe pain in the back, almost entire loss of power of erection, and a generally nervous and weakened condition of the entire system. A stricture at one-fourth of an inch from the meatus, which admitted a No. 18 French bulb, was cut, which on the following day enabled him to walk better than he had in 4 years, and in a short time all symptoms were relieved. The remainder of the urethra was entirely free from abnormal fibrous tissue.

CASE No. 149 was one of chronic serpiginous phagedena supplanted upon a chancroidal ulcer which had existed for 2 years when I saw him. The integument of all the lower part of the abdomen and pubes and probably some of the muscular tissue had been destroyed, but had granulated and healed. The penis was entirely gone, with an ulcer still remaining at the opening of the urethra, which was then at the scrotal junction. The scrotum and testicles were uninjured.

CASE No. 737 was also a venereal ulcer which began 3 years previous to his visit here. It had its beginning in the meatus and gradually, in spite of all medication, eroded its way through the dorsal portion of the glans penis, laying the entire glans wide open, then attacked the prepuce and had destroyed this tissue nearly around the entire organ to a distance of $1\frac{1}{2}$ inches from the corona. This may have been a case of mixed infection at the beginning, but I am of the opinion that it was a true chancre, as a clear syphilitic history dated from it, including the length of time after exposure before the appearance of the sore, and to this then was added the chronic serpiginous phagedena.

CASE No. 1040.—A strong healthy man; muscular system unusually well developed; very short in stature; with history of having had a bubo which was removed in its entirety 8 months before I saw him. While yet in the hospital he said a sore developed in his mouth, the exact location not known. He was given no medicine then and had taken none since. There had been no skin eruption so far as noticed. When seen the gums were swollen down on a level with the cutting edge of the teeth, and at places even beyond, were tender and had the appearance, especially behind the molars, of severe pyalism. This condition had been gradually developing since he left the hospital. The gums were quite firm, were not ulcerated, no granulations and no tendency to bleed except where they came in contact with the teeth; congested, bluish in color, and to a certain extent fibrous-like in appearance. The teeth were firm and continued so. Mercury and potassium iodid in enormous doses, with some local astringent applications, persisted in for 4 months, had relieved the trouble almost entirely when he left the city. I am unable to find this condition described; it was certainly syphilis, but was not a gingivitis gummosa as described by Morrow. It was a diffuse hyperplasia, a gingivitis interstitialis.

CASE No. 901.—Male; was one of most extensive condylomata about the anus. This condition followed a gonorrhea of the rectum which was contracted from a male friend. The growths were removed under anesthesia by the clamp and cautery where possible, and by the cautery alone where impossible to use both. There was no return.

CASE No. 886, with diagnosis of acute pemphigus vulgaris. The patient was a laborer, aged 31, who gave a possible history of syphilis 10 years previously; was not strong. From the time the eruption began until death occurred only 10 days elapsed. This condition is stated by all authors to be extremely rare, and by Zeisler to be classified rather as a febris bullosa, while Morrow in his *Atlas* describes it and classifies it as pemphigus, and reports a case in a man aged 33, but in his *System of Genito-Urinary Diseases, Syphilology and Dermatology* he says: "They would better be termed unprejudicedly as febris bullosa."

Below are given Charts II and III, in which is tabulated information that will show, to say the least, that gonorrhea is a very prevalent disease, and that it is contracted early in life.

CHART No. II.

	NUMBER	PER CENT
Number of males who had when seen, existing gonorrhea, or at some previous time had had the disease.	818	70.8
Number of males who had never had an attack of gonorrhea.	337	29.2
The above facts not ascertained in	229	
Females	27	
Total	1411	100
Number of attacks of gonorrhea as ascertained in 784 men	1886	
Average number of attacks to each individual	2.4	

CHART No. III.

Number of attacks not ascertained in		38
Total number of individuals		818
The average age at which gonorrhea was first contracted	21.8 yrs	

The information given in these tables was so unsatisfactorily obtained in some and seemed so unreliable

that the numbers were necessarily cut down considerably.

On a basis of 1,155 cases there were 818, or 70.8%, who had when seen or at some previous time had had an attack of gonorrhea, and 337, or 29.2%, had remained free from an infection by the gonococcus up to that time. In 229 the fact was either not ascertained or was deemed unreliable and in the 27 females it was not attempted; however, there were 17 out of the 27 women that were syphilitic subjects.

An attempt was also made to determine the number of attacks to each individual, from which it was deduced, that in 784 men there had been 1,886 cases of gonorrhea, an average of 2.4 attacks to each man. As these patients were of all ages, from puberty to old age, this gives, I think, a fairness in the average. Again, taking as a basis the 784 cases in whom the number of attacks was ascertained and the 337 who were found, if not virtuous, to at least have escaped gonorrheal infection, which seems to be abundantly liberal, there having been 34 discarded who were known to have had gonorrhea but the number of times not ascertained, we still have the appalling average of nearly 1.7 attacks to each individual.

It would seem that the memory of the first attack of gonorrhea would have impressed itself so indelibly upon the minds of each that the age at which it occurred could have been recalled at will; however, there were 58 discarded as being unsatisfactory. This leaves 760 to determine the average time of life at which the disease was first contracted, which gives us the age of 21.8 years. It will be noticed by referring to the chart that the age of 10 is the first on the list; I have seen one case in private practice, of a little boy 8 years old who had contracted the disease from a girl aged 12. We have another recorded at 12, three at 13, two at 14, and then the list rapidly swells until we reach 18, at which age the largest number of victims are recorded. It is a picture to the mind's eye of a perfect avalanche of boys, rushing pell-mell, in their eagerness to be the first to receive, to nurture and to propagate in the interests of posterity, the trouble-making germ known as the gonococcus. From 18 to 22 there is an apparent wavering, haste and eagerness have been partially supplanted by caution and fear. The early and unbounded passions of youth have been, to some extent, superseded by thoughts of employment, of gaining a livelihood, of the general responsibilities attendant upon manhood and finally of marriage. From 22 on down the list, as age increases, the number of first attacks rapidly decrease; however, we still have examples even up to the age of 57, and I may add that nearly all of the older patients recorded are of men who had contracted the disease after losing by death or otherwise their life-companions.

Many of the cases seen were lingering attacks that had existed oftentimes for years, in fact most all of the cases that come here for treatment do so because they have failed to be cured elsewhere. It will be noticed that in Chart I there were 76 cases of gleet and gonorrhea, the proportion of chronic cases were so much in advance of the acute that it is scarcely worth our while to mention the latter. Experience teaches us that a gonorrheal inflammation of the urethra, continued over a long period of time, or even but a comparatively brief time, if very severe, will and does cause granulations which as time passes become fibrillated and later begin to shorten or contract as in an ordinary scar. The
